The definitions of Alzheimer's disease and related dementias have been updated by the American Psychiatric Association. The prevalence of dementia increases with age; by age 85, between 30% and 40% have a dementia syndrome. Alzheimer's disease and vascular dementia, which often occur together based on pathologic studies, account for most dementias in older people. Dementia with Lewy bodies accounts for up to 25% of dementia and is characterized by Parkinsonian features early in the disease (as opposed to dementia in Parkinson's disease, which generally occurs years after the onset of Parkinson's), personality changes, alterations in alertness and attention, and visual hallucinations that can cause paranoia. Although most dementia syndromes are slowly progressive over several years, dementia is a terminal illness among patients who do not succumb to other comorbidities and results in devastating loss of cognition and function in the later stages.

Evaluation Regardless of setting, the new onset of delirium should be treated as a medical emergency because it can be the manifestation of an underlying critical illness. Figure 477-8 illustrates an overview of the assessment and management of impaired mental status and delirium in older hospitalized patients. The first step in the evaluation is to identify predisposing and precipitating factors such as hearing or visual impairment, symptoms of depression, laboratory abnormalities,

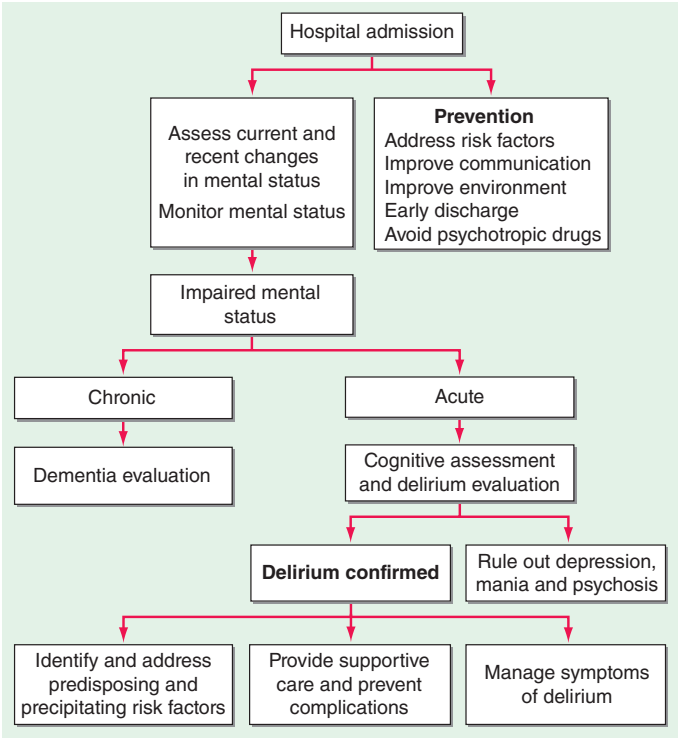

FIGURE 477-8 Algorithm depicting assessment and management of delirium in hospitalized older patients. *(From SK Inouye: Delirium in older persons. N Engl J Med 354:1157, 2006. Copyright © 2006 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

uncontrolled pain, infections, exacerbation of chronic illnesses, and history of alcohol or other substances use. The most validated evaluation for delirium is the Confusion Assessment Method, which requires an acute onset and fluctuating course *and* inattention *and* disorganized thinking *or* altered level of consciousness. Because the causes and risk factors for delirium are multifactorial, evaluation requires a careful history, physical examination, and selected laboratory studies based on the findings.

The benefits of screening older community-dwelling adults for cognitive impairment are controversial, but there are many interventions that may benefit patients and families early in the course of the disease (see below). Older patients in outpatient settings with complaints (or family reports of) early signs of cognitive impairment benefit from neuropsychological testing, which can help differentiate between MCI and dementia and identify concomitant factors such as depression and anxiety. The Mini-Cog is a sensitive screening tool for cognitive impairment, and consists of a three-item recall test and clock drawing. Further evaluation of dementia includes a comprehensive history and physical examination, functional status assessment (since the diagnosis depends on impaired function), a brain imaging study, and selected laboratory tests, including a complete blood count, comprehensive metabolic panel, thyroid function tests, vitamin B_{12} level, and, if suspected, tests for syphilis and human immunodeficiency virus antibodies.

Management Table 477-9 lists pharmacologic and nonpharmacologic management strategies for various underlying risk factors and causes of delirium. Every attempt should be made to avoid or discontinue any medication that may be worsening cognitive function in a delirious geriatric patient. This may not be possible, and in some patients, psychotropic drugs may be needed to treat delirium if the patient is a danger to themselves or others. Low-dose haloperidol (0.25–0.5 mg) is generally recommended; more sedating antipsychotics and benzodiazepines should be avoided unless the goal is to put the patient to sleep for a short time. If a benzodiazepine is used, it should be short-acting and in a low dose. Overall, multifactorial-proactive interventions and geriatric consultation have been associated with decreased incidence and duration of delirium in the hospital setting.

TABLE 477-9 Evaluation and Management of Delirium

CONTRIBUTING FACTORS	APPROACHES TO EVALUATION AND MANAGEMENT
Drugs	Consider the etiologic role of newly initiated drugs, increased doses, interactions, over-the-counter drugs, and alcohol; consider especially the role of high-risk drugs: lower the dose, discontinue the drug, or substitute a less psychoactive medication. Consider withdraw from chronic medications. Pay special attention to psychotropic medications.
Electrolyte disturbances	Assess for and treat, especially dehydration, hyponatremia and hypernatremia, hypothyroidism
Infection	Urinary tract infections, pneumonia, soft tissue infection
Visual/hearing impairment	Encourage the use of glasses and hearing aids if available.
Urinary and fecal disorders	Treat urinary retention and fecal impaction
Pulmonary disorders	Correct hypoxemia
Prevent or Manage Complications	
Urinary incontinence	Scheduled toileting
Immobility and falls	Encourage early mobilization to maintain baseline mobility
Pressure ulcers	Mobility and repositioning, nutrition
Sleep disturbances	Sleep hygiene, avoid sedatives, avoid unnecessary awakenings
Feeding disorders	Feeding assistance if necessary, aspiration precautions, liberalize diet if possible.
Maintain Patient Comfort and Safety	
Behavioral interventions	Staff education regarding de-escalation techniques for treatment of hyperactive delirium, facilitate family visitation if possible
Pharmacologic interventions	*Only* if the patient becomes a threat to himself or others and other interventions have failed
Restore Function	
Hospital environment	Adequate lighting, reduce noise
Cognitive reconditioning	Reorient patient frequently
Physical reconditioning	Physical and occupational therapy
Discharge planning	Assess new needs based on predischarge functional status, evaluate social support, coordinate transitions of care, medication reconciliation

Source: Adapted from ER Marcantonio: Delirium in hospitalized older adults. N Engl J Med 378:96, 2018.

Although the benefits of screening for cognitive impairment in community-dwelling older people are controversial, there are many nonpharmacologic interventions for older patients, their families, and other caregivers that may be beneficial (Table 477-10). Four basic approaches to the pharmacologic treatment of dementia are employed: (1) avoidance of drugs that can worsen cognitive function, mainly those with strong anticholinergic activity; (2) use of agents that enhance cognition and function; (3) drug treatment of coexisting depression, which is common throughout the course of dementia; and (4) pharmacologic treatment of complications such as paranoia, delusions, psychosis, and behavioral symptoms such as agitation (verbal and physical). The use of antipsychotics to treat the neuropsychiatric symptoms of dementia is controversial. Most experts and guidelines recommend avoiding these drugs and using nonpharmacologic strategies unless patients are a danger to themselves and others or if nonpharmacologic interventions have failed. Patients with new or worsening behavioral symptoms associated with dementia should have a medical evaluation to identify potentially treatable precipitating conditions. Pain may be especially hard to detect, and if suspected, a therapeutic trial of acetaminophen should be considered.

The effectiveness of cholinesterase inhibitors and memantine in improving function and quality of life in patients with various types of

TABLE 477-10 Key Principles in the Management of Dementia

- Optimize the patient's physical and mental function through physical activity and mind plasticity principles and activities
  - Treatment underlying medical and other conditions (e.g., hypertension, Parkinson's disease, depression)
  - Avoid use of drugs with central nervous system side effects (unless required for management of psychological or behavioral disturbances—see **Chap. 14**)
  - Assess the environment and suggest alterations, if necessary
  - Encourage physical and mental activity
  - Avoid situations stressing intellectual capabilities; use memory aids whenever possible
  - Prepare the patient for changes in location
  - Emphasize good nutrition
- Identify and manage behavioral symptoms and complications
  - Driving (consider a formal driving evaluation)
  - Wandering
  - Dangerous driving
  - Behavioral disorders
  - Depression
  - Agitation or aggressiveness
  - Psychosis (delusions, hallucinations)
  - Malnutrition
  - Incontinence
- Provide ongoing care
  - Reassessment of cognitive and physical function
  - Treatment of medical conditions
- Provide information to patient and family
  - Nature of the disease
  - Extent of impairment
  - Prognosis
- Provide social service information to patient and family
  - Local Alzheimer's association
  - Community health care resources (day centers, homemakers, home health aides)
  - Legal and financial counseling
  - Use of advance directives
  - Provide family counseling for:
    - Setting realistic goals and expectations
    - Identification and resolution of family conflicts
    - Handling anger and guilt
    - Decisions on respite or institutional care
    - Legal concerns
    - Ethical concerns
    - Consideration of palliative and hospice care
- Protect the caregiver from effects of caregiver stress

Source: Reproduced with permission from RL Kane et al (eds): *Essentials of Clinical Geriatrics*, 8th ed. New York, McGraw-Hill, 2017.

dementia is controversial, and the potential benefits of these drugs versus their risks and costs must be weighed carefully to provide optimal person-centered care. The best evidence for effectiveness of cholinesterase inhibitors is in delaying progression of Alzheimer's disease and increasing the time before institutional placement is needed. GI side effects can be problematic and include nausea, vomiting, and diarrhea; nightmares can be bothersome as well. In addition to these bothersome side effects, cholinesterase inhibitors can cause bradycardia and have been associated with syncope, injurious falls, and pacemaker placement. Memantine can cause dizziness, headache, confusion, and constipation. In one study, vitamin E was more effective than memantine in preventing functional decline in patients with Alzheimer's disease.

URINARY INCONTINENCE AND OVERACTIVE BLADDER

Epidemiology and Impact Urinary incontinence is curable or controllable in many geriatric patients, especially those who have adequate mobility and mental functioning. Even when it is not curable, incontinence can be managed in a manner that keeps people comfortable, makes life easier for caregivers, and minimizes the costs of caring for the condition and its complications. Approximately one in three women and 15–20% of men older than age 65 years have some degree of urinary incontinence. Between 5% and 10% of community-dwelling older adults have incontinence more often than weekly and/or use a pad for protection from urinary accidents. The prevalence is as high as 60–80% in many nursing homes, where residents often have both urinary and stool incontinence. Many older people (~40%) suffer from "overactive bladder," which may or may not include symptoms of incontinence. Symptoms of overactive bladder include urinary urgency (with or without incontinence), urinary frequency (voiding every 2 h or more often), and nocturia (awakening at night to void). If nocturia alone is the predominant symptom, the patient should be asked about sleep disorders (see next section). The pathophysiology, evaluation, and management of overactive bladder are essentially the same as for urge urinary incontinence.

Incontinence is associated with social isolation and depression and can be a precipitating factor in the decision to seek nursing home care when it cannot be managed in a manner that maintains hygiene and safety. In addition to predisposing to skin irritation and pressure ulcers, the most important potential complications of urinary incontinence and overactive bladder are falls and resultant injuries related to rushing to get to a toilet. Older people with gait disorders, especially those who have multiple episodes of nocturia or nocturnal incontinence, are at especially high risk for injurious. In addition to the bother of the condition to the older person or a caregiver, fall risk is a compelling reason for undertaking a diagnostic evaluation and specific treatment for incontinence and overactive bladder in the geriatric population.

Evaluation Internists should ask older people about symptoms of urinary incontinence because these symptoms are often hidden out of embarrassment or fear. Simple questions can help identify incontinent patients, such as "Do you have trouble with your bladder?" "Do you ever lose urine when you don't want to?" "Do you ever wear padding to protect yourself in case you lose urine?" (Table 477-3). A substantial number of older people will respond "no" to the first two questions but "yes" to the third one.

Several points are worth noting for the practicing internist. The history and physical examination should focus on identifying potentially reversible causes and contributing factors **(Table 477-11)** and identifying the specific lower urinary tract symptoms. A simple, three-item validated questionnaire can assist in distinguishing between the most common types of incontinence **(Fig. 477-9)**. Key aspects of the history and physical exam are outlined in **Table 477-12**. Among older women, the most common symptoms are a mixture of urge and stress incontinence **(Fig. 477-10)**; urge is usually the more bothersome. Stress incontinence can often be objectively observed during a physical examination with a comfortably full bladder by having the patient cough in the standing position; leakage of urine simultaneously with coughing indicates that stress incontinence is present. Older men commonly have symptoms associated with overactive bladder and/or symptoms of voiding difficulty (hesitancy, poor or intermittent urinary stream, postvoid dribbling); the overactive bladder symptoms are usually more bothersome. These symptoms overlap with those of both benign and malignant disorders of the prostate, and many internists may choose to consult a urologist for further management **(Chap. 87)** because a urinary flow rate and postvoid residual determination, and further evaluation if malignancy is suspected, are helpful in determining therapy.

Most older patients with symptoms of incontinence should have a postvoid residual determination, especially men, diabetics, those with neurologic disorders, and those with symptoms of voiding difficulty, because incomplete bladder emptying is common in older patients and is difficult to detect by history and physical examination alone. There is no specific cutoff for an abnormal postvoid residual; the test must be done with a full bladder, and straining during the test can alter the results. In older patients, a postvoid residual between 0 mL and 100 mL

TABLE 477-11 Reversible Conditions That Cause or Contribute to Urinary Incontinence and Overactive Bladder Symptoms in Older People

CONDITION	MANAGEMENT
Lower urinary tract conditions	
Urinary tract infection (symptomatic with frequency, urgency, dysuria, etc.)	Antimicrobial therapy
Atrophic vaginitis/urethritis	Topical estrogen (not a primary treatment for incontinence but may help prevent recurrent infections and ameliorate symptoms of overactive bladder; oral estrogens can cause or worsen incontinence)
Stool impaction with irritation of bladder/urethral innervation and/or partial bladder outlet obstruction	Disimpaction; appropriate use of stool softeners, bulk-forming agents, and laxatives if necessary; implement bowel regimen
Increased urine production	
Metabolic (hyperglycemia, hypercalcemia)	Better control of diabetes mellitus
	Therapy for hypercalcemia depends on underlying cause
Excess caffeine or fluid intake	Reduction in intake of caffeinated beverages; reduction in fluid intake (most older people with incontinence or overactive bladder self-restrict fluid intake)
Volume overload with increased urine production at night	Support stockings
Venous insufficiency with edema	Leg elevation
	Sodium restriction
	Diuretic therapy (late afternoon dose may be effective)
Congestive heart failure	Medical therapy
Impaired ability or willingness to reach a toilet	
Delirium	Diagnosis and treatment of underlying cause(s)
Chronic illness, injury, or restraint that interferes with mobility	Regular toileting
	Use of toilet substitutes
	Environmental alterations (e.g., bedside commode, urinal)
	Remove restraints if possible
Psychological (depression, anxiety)	Appropriate nonpharmacologic and/or pharmacologic treatment
Drug side effects	Remove offending drug(s) if feasible; modification of dose, frequency, or timing may also reduce symptoms for some drugs:
	Diuretics (polyuria, frequency, urgency)
	Anticholinergics (constipation, incomplete bladder emptying)
	Psychotropic drugs
	Tricyclic antidepressants (anticholinergic effects)
	Antipsychotics (immobility, sedation)
	Sedative-hypnotics (immobility, sedation)
	Narcotic analgesics (constipation, incomplete bladder emptying)
	α-Adrenergic blockers (urethral relaxation)
	α-Adrenergic agonists (urethral contraction and potential incomplete bladder emptying)
	Cholinesterase inhibitors (urinary frequency, urgency)
	Angiotensin-converting enzyme inhibitors (cough precipitating stress incontinence)
	Calcium channel blockers, gabapentin, pregabalin, glitazones (edema with nocturia)
	Alcohol (polyuria, frequency, urgency, sedation, delirium, immobility)
	Caffeine (polyuria, bladder irritation)

Source: Reproduced with permission from RL Kane et al (eds): *Essentials of Clinical Geriatrics*, 8th ed. New York, McGraw-Hill, 2017.

is normal, a residual between 100 and 200 mL must be interpreted based on symptoms, and a value >200 mL is abnormal and usually influences treatment.

Management Patients who meet certain criteria should be referred for further urologic, gynecologic, and/or urodynamic evaluation before initiating specific therapy. Examples include history of lower urinary tract surgery or radiation or recurrent symptomatic urinary tract infections, marked pelvic prolapse on physical examination of a woman, suspected prostate cancer, and sterile hematuria.

Potentially reversible conditions should be addressed, including the many types of medications that can affect bladder function, which should be eliminated if possible (Table 477-11). **Table 477-13** lists treatments for different types of incontinence. Many patients respond well to properly taught and adhered to behavioral interventions. Physical therapists and nurses who specialize in treating lower urinary tract symptoms can be very helpful and should be consulted if available. Pharmacologic treatment of incontinence and overactive bladder is dictated by the innervation of the lower urinary tract. α-Adrenergic stimulation increases tone in the smooth muscle of the urethra; thus, α agonists have been used to treat stress incontinence in women (although none are approved by the U.S. Food and Drug Administration for this indication), and alpha blockers are used to decrease urethral tone in men with overactive bladder associated with prostate enlargement. Anticholinergic/antimuscarinic agents and β-3 stimulation inhibit bladder contraction and are used for overactive bladder and urge incontinence. In men with overactive bladder and normal postvoid residual who do not respond to an alpha blocker (with or without a 5α-reductase inhibitor), adding an antimuscarinic or β-3-adrenergic agent may improve symptoms with a very low risk of causing urinary retention. Patients with severe cognitive impairment and/or immobility can generally be managed effectively by prompted voiding and/or incontinence undergarments, as long comfort, dignity, and safety are maintained.

SLEEP DISORDERS

Sleep disorders are discussed in more detail for the general adult population in **Chap. 31**. Because they are so common and have some unique features in older patients, they are discussed briefly here.

The 3IQ is a patient questionaire that helps your doctor distinguish urge incontinence from stress incontinence. It should take no more than a couple of minutes. Complete the quiz and bring it to your next appointment.

1. During the last 3 months, have you leaked urine (even a small amount)?

☐ **Yes** ☐ **No** (if this response is marked, the 3IQ test is complete)

2. During the last 3 months, did you leak urine (check all that apply):

☐ When you were performing some physical activity, such as coughing, sneezing, litting, or exercising?

☐ When you had the urge or the feeling that you needed to empty your bladder, but you could not get to the toilet fast enough?

☐ Without physical activity and without sense of urgency?

3. During the last 3 months, did you leak urine most often (check only one):

☐ When you were performing some physical activity, such as coughing, sneezing, litting, or exercising?

☐ When you had the urge or the feeling that you needed to empty your bladder, but you could not get to the toilet fast enough?

☐ Without physical activity and without sense of urgency?

☐ About equally as often with physical activity as with a sense of urgency?

Definitions of type of urinary incontinence are based on responses to question 3.

Response to Question 3	Type of incontinence
Most often with physical activity	Stress only or stress predominant
Most often with the urge to empty the bladder	Urge only or urge predominant
Without physical activity or sense of urgency	Other cause only or other cause predominant
About equally with physical activity and sense of urgency	Mixed

FIGURE 477-9 The 3 Incontinence Questions (3IQ) Assessment Tool. *(From Annals of Internal Medicine, JS Brown JS et al: The sensitivity and specificity of a simple test to distinguish between urge and stress urinary incontinence. 144 (10):715, 2006. Epidemiology and Impact Aging is associated with multiple changes in sleep architecture as well as multiple diseases and disorders that can disrupt sleep. Thus, complaints of sleep difficulty are common in older adults. Consequences of sleep difficulty include lower health-related quality of life, increased medication use, more cognitive decline, and greater health care utilization. Four types of primary sleep disorders are common in the geriatric population: insomnia, sleep-disordered breathing due to obstructive sleep apnea (OSA), restless leg syndrome (RLS), and periodic leg movements in sleep (PLMS). Complaints of bothersome insomnia—the inability to fall asleep or stay asleep despite a conducive environment—increase with age and occur in close to 30% of people older than 65. Insomnia is commonly associated with depression, anxiety, alcohol intake, and ingestion of caffeinated beverages later in the day. OSA occurs in ~10% of older adults but is probably underreported and underdiagnosed. It is associated with medical comorbidities, such as obesity and congestive heart failure. RLS occurs in 5–10% of adults, and its prevalence increases in those older than 70. It is almost twice as common in women than men; family history, iron deficiency, and intake of antihistamines and most antidepressants are risk factors. PLMS can be found in up to 45% of older people but is often of unknown clinical consequence and remains undiagnosed.

Evaluation Older people should be screened for sleep difficulty with questions such as, "Do you often feel sleepy during the day?" and "Do you have difficulty falling asleep at night?" Further evaluation of the nature and impact of the complaints can be accomplished with standardized questionnaires (Table 477-3). Patients with significant sleep complaints should be asked about conditions that can interrupt sleep, such as nocturia, gastroesophageal reflux, chronic pain, and caffeine and alcohol intake. Specific questions characterizing the complaints should include inquiring about loud snoring (for OSA), the urge to move legs associated with uncomfortable sensations (RLS), and leg movements during sleep (PLMS; which may result in kicking a bed partner).

Management Patients suspected of having OSA, RLS, or PLMS should be referred for formal sleep evaluation. While hypnotics are among the most commonly prescribed drugs in the geriatric population, nonpharmacologic management of sleep should be the initial and primary approach, as many patients can benefit from properly taught and adhered to interventions **(Table 477-14)**. Benzodiazepine hypnotics should be avoided whenever feasible because they are associated with next-day hangover effects, which may manifest as cognitive impairment and can precipitate falls and car crashes and rebound insomnia. Patients with sleep-onset insomnia may respond to melatonin or low-dose trazadone, both of which are safer than using a benzodiazepine chronically.

FRAILTY

Definition, Epidemiology, and Impact The term *frail* is often used to describe older adults. However, over the past several years, *frailty* has been defined as a specific syndrome, and the word *frail* is

TABLE 477-12 Key Aspects of the History and Physical Examination of an Older Patient with Symptoms of Urinary Incontinence and Overactive Bladder

History
Active medical conditions, especially neurologic disorders, diabetes mellitus, congestive heart failure, venous insufficiency
Medication review for drugs that can contribute (see Table 477-11)
Fluid intake pattern
Type and amount of fluid (especially caffeine and fluids before bedtime)
Past genitourinary history, especially childbirth, surgery, dilatations, urinary retention, recurrent urinary tract infections
Symptoms of incontinence
Onset and duration
Type—stress vs urge vs mixed vs other (see Fig. 477-10)
Frequency, timing, and amount of incontinence episodes and of continent voids (a voiding diary may be useful)
Other lower urinary tract symptoms
Irritative—dysuria, frequency, urgency, nocturia
Voiding difficulty—hesitancy, slow or interrupted stream, straining, incomplete emptying
Other—hematuria, suprapubic discomfort
Other symptoms
Neurologic (indicative of stroke, dementia, parkinsonism, normal-pressure hydrocephalus, spinal cord compression, multiple sclerosis)
Psychological (depression)
Bowel (constipation, stool incontinence)
Symptoms suggestive of volume-expanded state (e.g., lower extremity edema, shortness of breath while horizontal or with exertion)
Environmental factors
Location of bathroom
Availability of toilet substitutes (e.g., urinal, bedside commode)
Perceptions of incontinence
Patient's concerns or ideas about underlying cause(s)
Most bothersome symptom(s)
Interference with daily life
Severity (e.g., "Is it enough of a problem for you to consider surgery?")
Physical Examination
Mobility and dexterity
Functional status compatible with ability to self-toilet
Gait disturbance (e.g., that may suggest parkinsonism, normal-pressure hydrocephalus)
Mental status
Cognitive function compatible with ability to self-toilet
Motivation
Mood and effect
Neurologic
Focal signs (especially in lower extremities) that could suggest a central nervous system condition
Signs of parkinsonism
Sacral arc reflexes (e.g., loss of perianal sensation or an anal wink in response to perianal stimulation)
Abdominal
Bladder distension[a]
Suprapubic tenderness
Lower abdominal mass
Rectal
Perianal sensation
Sphincter tone (resting and active)
Impaction
Masses
Size and contour of prostate (neither is diagnostic of urethral obstruction)
Pelvic
Perineal skin condition
Perineal sensation
Atrophic vaginitis (friability, inflammation, bleeding)
Pelvic prolapse or mass
Other
Lower extremity edema or signs of congestive heart failure (if nocturia is a prominent complaint)

[a]Clinically significant degrees of urinary retention may be difficult to detect on physical examination; many incontinent patients should have a postvoid residual determination done by ultrasound (see text).

Source: Reproduced with permission from RL Kane et al (eds): *Essentials of Clinical Geriatrics*, 8th ed. New York, McGraw-Hill, 2017.

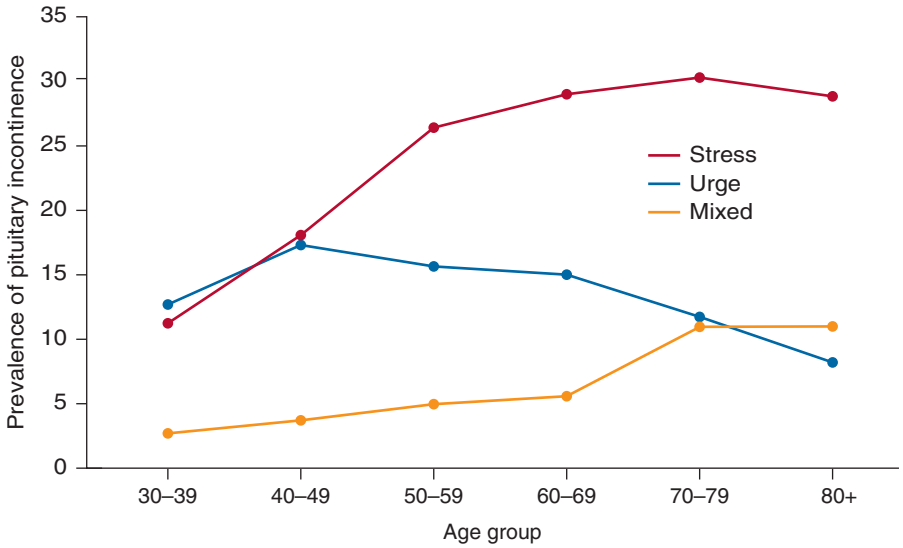

FIGURE 477-10 Rates of urge, stress, and mixed incontinence, by age group, in a sample of 3552 women. *Based on a sample of 3553 participants. *(Adapted from JL Melville, W Katon, K Delaney, K Newton: Urinary incontinence in US women: A population-based study. Arch Intern Med 165:537, 2005.)*

more appropriately used to describe people who meet frailty criteria. Frailty is a state of increased vulnerability characterized by a decline in physiologic reserve and function across multiple systems. Many different definitions and tools to define frailty exist. Fried criteria based on the Cardiovascular Health Study (see below) and the Frailty Index (a list of several specific diagnoses developed by Rockwood and colleagues) have been used to screen for frailty in clinical settings. The importance of screening for frailty is to mitigate disability and adverse health outcomes as well as for the assessment of benefits and risks of treatment decisions. The prevalence of frailty is higher among women and increases with age. The overall prevalence of frailty in community-dwelling adults aged 65 and older varies considerably but, on average, is 10–14% depending on the definition. The prevalence of frailty increases with age, reaching close to 16% in individuals age 80–84 and 26% in those aged 85 or older. In older hospitalized patients and institutionalized older people, the frailty prevalence varies from about 27% to up to 80%. Irrespective of the definition, the prevalence of frailty shows a U-shaped relationship with body mass index (BMI), with higher levels of frailty in individuals with both low and very high BMI.

Pathophysiology Frailty is a three-dimensional process that involves changes at the cellular, physiologic, and phenotypical levels. At the cellular level, frailty manifests as changes in mitochondrial function, the development of oxidative stress and DNA damage, and telomere shortening and stem cell exhaustion. These changes at the cellular level result in physiologic alterations including inflammation, cell mediator dysfunction such as low production of nitric oxide by the endothelium, sarcopenia, and energy unbalance. Fried and colleagues conceptualize frailty as a vicious circle of declining energetics and reserve, whose elements represent both the diagnostic criteria for the syndrome identification and the core elements of its pathophysiology. The process manifests phenotypically as overall decline in physical function and cognitive impairment. In particular, the phenotype of frailty has been defined by Fried and colleagues by the five following characteristics: unintentional weight loss, weakness, exhaustion, slowness, and low activity (with specific operational definitions of each).

Management Although there is conflicting evidence regarding the effectiveness of specific interventions to treat or prevent frailty, person-centered physical activity programs and nutritional supplementation appear to improve components of frailty such as muscle strength, gait speed, and overall mobility. In addition, optimizing the management

TABLE 477-13 Primary Treatments for Different Types of Geriatric Urinary Incontinence

TYPE OF INCONTINENCE	PRIMARY TREATMENTS
Stress	Pelvic muscle (Kegel) exercises
	Other behavioral interventions including timed voiding and double voiding to avoid residual urine
	α-Adrenergic agonist (none are approved by the U.S. Food and Drug Administration for this purpose)
	Topical estrogen to strengthen periurethral tissue (not effective alone; oral estrogens contraindicated)
	Periurethral injections to provide bulking and support
	Surgical bladder neck suspension or sling for severe incontinence, based on patient preference
Urge and overactive bladder symptoms	Pelvic muscle (Kegel) exercises
	Other behavioral interventions: timed voiding and double voiding to avoid residual urine
	Antimuscarinic and β-3-adrenergic drugs
Incontinence with incomplete bladder emptying	α-Adrenergic antagonists in men with a 5α-reductase inhibitor if the prostate is enlarged); an antimuscarinic or β-3-adrenergic drug can be added if unresponsive to the α-adrenergic agonist
	Bladder training, double voiding
	Intermittent catheterization
	Indwelling catheterization in selected patients in whom risks and discomforts of urinary retention outweigh risks of a chronic indwelling catheter
Incontinence with impaired physical and/or cognitive function	Behavioral interventions (prompted voiding, habit training)
	Environmental manipulation including use of urinal or bedside commode, safe lit path to bathroom)
	Incontinence undergarments and pads

TABLE 477-14 Nonpharmacologic Management of Insomnia in Older Adults

Sleep Hygiene Rules
Check effect of medication on sleep and wakefulness
Avoid caffeine, alcohol, and cigarettes after lunch
Limit liquids in the evening
Keep a regular bedtime-waketime schedule
Avoid naps or limit to 1 nap a day, no longer than 30 min
Spend time outdoors (without sunglasses), particularly in the late afternoon or early evening
Exercise—but limit exercise immediately before bedtime
Instructions for Stimulus-Control Therapy
Only go to bed when tired or sleepy
If unable to fall asleep within 20 min, get out of bed (and bedroom if possible); while out of bed, do something quiet and relaxing
Only return to bed when sleepy
If unable to fall asleep within 20 min, again get out of bed
Repeat these behaviors until able to fall asleep within a few minutes
Get up at the same time each morning (even if only a few hours of sleep)
Avoid naps

Source: Adapted from JB Halter et al (eds): *Hazzard's Geriatric Medicine and Gerontology*, 7th ed. New York, McGraw-Hill, 2016.

of chronic conditions, medication management including mitigation of polypharmacy, and identifying the individual's priorities could lead to reversing or slowing progression of frailty.

ELDER ABUSE AND NEGLECT

Epidemiology and Impact The incidence of elder abuse and neglect and self-neglect are unknown because they are often unrecognized. The best data suggest that the incidence over 12 months is at least 8–10%. Abuse and neglect can result in physical injuries and related pain, worsening of chronic medical conditions, dehydration and pressure ulcers, emotional distress, and loss of income and savings.

Evaluation Because abuse and neglect are underreported, are unsuspected, and have such devastating consequences, older adults should be screened (without the presence of caregivers) with questions such as, "Do you ever feel unsafe where you live?" "Has anyone ever threatened or hurt you?" "Has anyone been taking your money without your permission?" (Table 477-3). Table 477-15 outlines the definitions, symptoms and signs, and key aspects of evaluating suspected abuse and neglect.

TABLE 477-15 Elder Abuse and Neglect

CATEGORY	DEFINITION AND EXAMPLES	SYMPTOMS AND SIGNS	KEY ASPECTS OF EVALUATION
Physical Abuse	Acts of violence that may result in pain, injury, or impairment • Pushing, slapping, hitting, force-feeding • Improper positioning or use of restraints • Improper use of medications	Abrasions Lacerations Bruises Fractures Use of restraints Burns Pain Depression Delirium or onset or worsening of dementia-related behavioral symptoms	The interview should be conducted alone with the patient; it may reveal discordant histories or findings inconsistent with the history provided by the caregiver. Ankles and wrists should be examined for abrasions suggestive of the use of restraints. Findings that are discordant with the mechanism of injury reported or multiple injuries in various stages of healing should raise the suspicion of abuse. Injuries to the head, neck, and upper arms occur in victims of physical elder abuse but must be distinguished from accidental injuries. Jaw and zygomatic fractures are more likely to be sustained from a punch than from a fall, which more typically result in fractures to orbital and nasal bones.
Psychological or Verbal Abuse	Conduct that causes mental or emotional distress • Verbal harassment or intimidation • Threats of punishment or deprivation • Isolation	Direct observation of verbal abuse Subtle signs of intimidation, such as deferring questions to a caregiver or potential abuser Evidence of isolation Depression, anxiety, or both	Assess the size and quality of the patient's social network (beyond the suspected abuser). Conduct standardized assessments of depression, anxiety, and cognition, directly or through referral. Ask specifically about verbal or psychological abuse with questions such as "Does your relative/caregiver ever yell or curse at you?"; "Have you been threatened with being put into a nursing home?"; or "Are you ever prevented from seeing friends and family members whom you wish to see?"
Financial Abuse	Misuse of the person's income or resources for the financial or personal gain of a caregiver or advisor • Stealing money or possessions • Denying a home • Coercing to sign contracts or spend money	Inability to pay for medicine, medical care, food, rent, or other necessities Failure to renew prescriptions, adhere to medication regimens or other treatments, or keep medical appointments Malnutrition, weight loss, or both, without an obvious medical cause Evidence of poor financial decision-making Firing of home care or other service providers by abuser Unpaid utility bills Initiation of eviction proceedings	Ask about financial exploitation with questions such as "Has money or property been taken from you without your consent?"; "Have your credit cards or automated teller machine card been used without your consent?"; and "At the end of the month, do you have enough money left for food and other necessities?" Abrupt changes in financial circumstances of the caregiver in either direction may herald an increased risk of financial exploitation or exploitation already under way. Abuse of the power of attorney; if the person with power of attorney or health care proxy is suspected of not acting in the best interest of the patient, documents necessary to ensure that the assumption of fiduciary responsibilities is authorized.
Sexual Abuse	Sexual coercion or assault	Bruising, abrasions, lacerations in the genital or anal areas or abdomen Newly acquired sexually transmitted diseases, especially in nursing home Urinary tract infection	Inquire directly about sexual assault or coercion. For patients with dementia, direct queries to caregivers about hypersexual behavior as part of a larger history regarding dementia-related behaviors and assess patient's capacity for decision-making about sexual activity. If indicated, refer to an emergency department for assessment for sexual assault and collection of specimens (forensic evidence should be collected by experienced professionals, such as nurses who have undergone Sexual Assault Nurse Examiners [SANE] training).
Neglect (by caregiver or self-neglect)	Failure to provide the materials, supplies, food and drink, or services necessary for optimal functioning or to avoid harm	Malnutrition Dehydration Poor hygiene Pressure ulcers Nonadherence to medication regimen or other treatments Worsening of dementia-related behavioral symptoms	Interview primary caregiver about his or her understanding of the nature of the patient's care needs and how well care is being rendered. Neglect by a caregiver may be intentional or unintentional. Assess hygiene, cleanliness, and appropriateness of dress. Examine the skin for pressure ulcers, infections, and infestations. Assess nutrition and hydration, including measuring body mass index and blood urea nitrogen and creatinine to assess hydration.

Management In addition to treating the physical, medical, and emotional consequences, patients suspected of elder abuse or neglect should be reported to the appropriate local or state agency to investigate and ensure the patient's safety. The reader is referred to two reviews of this topic for further information on specific aspects of management.

SEVERE ACUTE RESPIRATORY SYNDROME CORONA VIRUS (SARS-COV-2) INFECTION AND COVID-19 DISEASE

(See Chaps. 122 and 199) The COVID-19 pandemic has disproportionately affected the older population, especially those residing in nursing homes and assisted living facilities. Compared with those between the ages of 18 and 29 years old, older adults are at greater risk for adverse outcomes after infection with SARS-CoV-2, especially those with multiple comorbidities. Mortality ratios are 200 and 600 times higher among those aged 75–84 and >85, respectively, with 8 and 13 times the risk of hospitalization. While some older patients survive with minimal symptoms and residual effects, others deteriorate rapidly into respiratory distress, and if they survive, many have prolonged effects in multiple systems. For these reasons, patients in this age group should have an advance care planning discussion regarding goals of care if they get infected with SARS-CoV-2 or similar infections that cause widespread life-threatening illnesses. Screening older adults for SARS-CoV-2 is challenging as some of the cardinal symptoms are often not present, especially among frail older adults living in LTC institutions. For example, temperature elevations do not reach threshold for fever of 38°C in a significant portion of older adults with COVID-19.

The pandemic has had devasting consequences in nursing homes and assisted living facilities. Tragic outbreaks causing dozens of hospitalizations and deaths in a single facility over a short period of time have been widely reported, even in the highest quality facilities. Staff and clinicians working in nursing homes and assisted living in many areas have suffered from a shortage of accurate testing capability and personal protective equipment that has put their own health and the health of their families at risk, especially in facilities that serve more diverse and socioeconomically disadvantaged populations. Because of restrictions on visitation and social distancing policies, the pandemic has had a tremendous negative psychological effect on residents and their loved ones. Owners and operators of these institutions have suffered severe financial consequences, and many may not be able to continue operating without ongoing state and/or federal assistance.

COVID-19 has taught us many lessons for the future care of our growing geriatric population. These lessons go well beyond the need for intensive education on and implementation of intensive infection control policies and procedures. The way that our society organizes and funds care for vulnerable older people who cannot live independently, trains health care professionals to care for this population, and measures the quality of care needs careful rethinking to meet the needs of older people over the next several decades.

END-OF-LIFE AND PALLIATIVE CARE

End-of-life and palliative care are critical aspects of caring for the geriatric population and require a comprehensive, person-centered approach. End-of-life and palliative care are addressed in detail in **Chap. 12**, and pain management is addressed in **Chap. 13**. For geriatric patients, limited life expectancy is a critical factor to consider when making end-of-life care decisions. General principles of decision-making are especially relevant when considering palliative and/or end-of-life care in older patients (Fig. 477-5). Decision-making becomes complicated, however, among older patients with multimorbidity. Without a clear terminal diagnosis, when to start palliative care/end-of-life care could be challenging. While it is sometimes clear when an older patient has a terminal condition, such as end-stage congestive heart failure or chronic obstructive pulmonary disease, many older patients with multimorbidity have combinations of conditions of varying severity. Moreover, neurogenerative disorders, including most forms of dementia, Parkinson's disease, and patients with multiple strokes, commonly have a gradually progressive course, and it can be challenging to determine when discussions about palliative and end-of-life care should be initiated. Dementia, however, should be considered a terminal illness in the advanced stages.

Internists should play a pivotal role in making the decision when to initiate these discussions and should be proactive in encouraging patients and their families to execute advance directives before a health care crisis occurs. There are good data that bear on some of the decisions. For example, the survivability of cardiopulmonary resuscitation (CPR) in hospitalized patients age 65 and older is <20%; among the old-old with multimorbidity, it is much lower. The survivability of CPR in nursing home residents is almost zero, making it a futile intervention for most in this setting. Data and recommendations of major organizations suggest that enteral feeding tubes should not be placed in patients with end-stage dementia (Table 477-2). Tools for the estimation of prognosis such as ePrognosis, for holding conversations with older people and their families about advance care planning, and for documentation of advance directives (e.g., living will, durable power of attorney for health care, Physician Orders for Life-Sustaining Treatments [POLST], and other order sets) will assist internists in paying careful attention to factors that contribute to person-centered care and in dealing with these challenging issues in end-of-life geriatric care.

478 Approach to Medical Consultation

Jeffrey Berns, Jack Ende

Effective health care requires teams of generalists and specialists with complementary expertise. Many clinical conditions require the input of more than one clinical provider, either because the diagnosis and recommended treatment is uncertain or because a patient may have multiple diseases that may be best managed by involving multiple specialists.

To *consult* is to seek advice from someone with expertise in a particular area, whereas *consultation* refers to the meeting or comparable outcome arising from that request. Medical consultation takes several forms. Its most traditional forms include in-hospital consultation, in which physicians provide recommendations, typically recorded in the medical record, or perform procedures for a hospitalized patient, and outpatient consultations, in which patients are seen in the office setting. More contemporary forms of consultation include e-consultations, telemedicine evaluations (see "Consultation Involving Telemedicine," below), and remote medical second opinions. In these forms, the consultant may not actually see the patient but, nonetheless, assumes the responsibility of evaluating the patient's clinical condition, assessing and analyzing pertinent clinical data, and offering a synthesis and appropriate recommendations.

While forms of medical consultation evolve, basic responsibilities associated with medical consultation endure. These responsibilities can be divided into those that fall to the requesting physician or nonphysician practitioner; the consultant, who provides the consultation; and the health system, hospital, or organization that must support this important medical encounter **(Table 478-1)**.

TABLE 478-1 Stakeholder Responsibilities in the Medical Consultation Process

REFERRING PHYSICIAN OR PROVIDER	CONSULTANT PHYSICIAN	HEALTH SYSTEM, HOSPITAL, OR CARE ORGANIZATION
• Ensure patient participation and engagement • Be specific regarding clinical question and desired outcome • Communicate level of urgency • Avoid consulting for nonclinical purposes	• Maintain standards of professionalism, including those pertaining to availability, communication, respect, and collegiality • Appreciate levels of urgency and respond appropriately • Assemble and develop one's own database • Be specific in synthesis and recommendations • Understand desired outcomes, including arrangements for follow-up • Communicate with referring provider in whatever manner is mutually desirable	• Maintain adequate specialty workforce to enable appropriate access • Support systems for efficient exchange of clinical information • Develop culture of collegiality and team-based care

RESPONSIBILITIES OF THE REQUESTING CLINICIAN

Before requesting a consultation, the physician or other provider should ensure that the patient endorses the purpose of the consultation, understands the role of the consultant, and anticipates the likely outcomes of the encounter. Further responsibilities of the requesting physician include being specific and communicating clearly the reason for the consultation. Vague messages such as "Please evaluate" are not as helpful as more specific inquiries such as "What is the cause of the declining kidney function?" or "How should this asymptomatic pulmonary nodule be evaluated?" To the extent possible, the requesting physician should provide the relevant clinical information, summarized as succinctly as possible. Urgency should be clearly conveyed, typically with a phone call or other direct communication.

The requesting physician should be explicit regarding the intended outcome of the consultation, i.e., is this for a single evaluation or ongoing co-management? Communication between the requesting and the consulting physicians is paramount. Whether this communication includes direct contact is less important than that the relevant information and desired outcome be explicit and clear, regardless of communication medium. Consultations should be requested for clinical purposes and always directed to qualified consultants; they should not be driven by entrepreneurial or relationship-building purposes. Another responsibility of the referring physician is not to "overconsult." Medical care should be focused on value, not volume.

RESPONSIBILITIES OF THE CONSULTANT

Just as the referring physician should attend to clear and explicit communication, so too should the consultant follow the precepts of effective interactions between professionals, which include courtesy, availability, and clarity. Particularly on the inpatient service, where consultants may receive several requests each day, it is important that the incoming consultations are triaged and dispatched as clinically appropriate. Consultants also need to determine the requested level of involvement going forward and not assume that long-term co-management is being sought. While consultants can and should make use of available clinical data, they should also assemble independently their own database, including taking a history, performing a physical exam, and reviewing pertinent laboratory, imaging, and pathology studies. Absent that, they may be unable to provide an independent and actionable synthesis. Just as the referring physician needs to be clear and concise, so too should the consultant be specific and focused in the recommendations provided. "Possible malignant ascites" is less helpful than, "I will arrange for paracentesis to exclude the possibility of malignant ascites." For the most part, recommendations to "consider" some diagnosis or test are less helpful than more specific and concrete advice. Some referring physicians wish to be called after a patient is seen; others prefer that communication be handled as part of the medical record. How this communication is handled must also align with the complexity and urgency of the consultation and clinical circumstances.

RESPONSIBILITIES OF HEALTH SYSTEMS, HOSPITALS, AND MEDICAL ORGANIZATIONS

Health systems, hospitals, and medical organizations also have responsibilities in the consultation process. This responsibility includes ensuring that qualified consultants are accessible and available on the medical staff. Consultations within a single system are aided by common shared electronic medical records, particularly when consultations originate in the hospital, but then also involve care in the outpatient setting. Finally, health care entities should strive to foster a culture of team-based care and collegiality. Reimbursement for consultations varies among payors and may have implications for self-pay or unreimbursed expenses for providers or health systems. While it is important to understand reimbursement models, the clinical needs of the patient should be prioritized.

Curbside Consults Curbside consults are requests from one physician to another for an informal and unwritten opinion about a specific patient care matter. They are typically limited in scope, mostly regarding management or questions regarding procedures, and developed from information provided by the consulting physician and perhaps the medical record (such as labs and imaging studies). Although often viewed as convenient, efficient, and a common aspect of clinical care, without a comprehensive review of the record or any direct contact with the patient, curbside consults have been found to often be incomplete or even flawed. It is not uncommon for the question being asked to be deemed too complex for a curbside consult or for it not to be the actual or only issue the consultant feels needs to be addressed. As a general rule, curbside consults should be avoided. While medicolegal liability is often cited as a reason to limit curbside consults, the risk is actually negligible as U.S. courts have ruled that curbside consults do not establish a doctor-patient relationship necessary for creating the basis for medical malpractice litigation. An important exception, however, is when a curbside consult is provided by a resident or fellow in training; in this circumstance, the trainee's supervising physician, whether aware of the curbside consult or not, is responsible for the recommendations of the trainee.

Advice Related to curbside consultation, but decidedly different, are instances when one physician reaches out to another, often one in another specialty, for advice. Examples include an internist turning to a radiologist for guidance on what is the most appropriate imaging study to diagnose a deep tissue abscess; a general internist asking a gastroenterologist for advice on management of acute diverticulitis; a hospitalist asking a neurologist for guidance on management of a patient with Parkinson's disease who is NPO; or a nephrologist asking an infectious disease specialist about immunizations in a kidney transplant recipient.

Outreach such as this is typically triggered by a specific patient encounter, but the request is more for general information that the requesting physician may use for the encounter at hand as well as for similar encounters going forward. Thus, reaching out for advice differs from formal consultation and from curbside consultation, which are specific for a particular patient. As such, requests for advice fall within the realm of collegial communication and not necessarily within that of clinical consultation per se.

Second Opinions Physicians may find themselves providing consultations requested by patients who have already been evaluated for the same problem by another physician. Not a "consult" in the usual context of one physician referring a patient to another, the service provided by the consultant is, nonetheless, very much aligned with a physician-referred consult. Second opinions, which often are encouraged by the patient's physician, may be sought by patients for reassurance that a diagnosis and treatment recommendation are correct, out of dissatisfaction with the initial physician, or with the hope of an entirely different opinion and recommendation. The physician providing the second opinion should strive to understand the patient's motivations for seeking the additional opinion. While a second opinion may have been initiated by the patient rather than referral from another physician, it is recommended that the consulting physician communicate with the patient's primary physician, as would be done following a standard consultation, unless the patient insists otherwise. In addition, professional behavior in how the consulting physician refers to the recommendations or actions of previous physicians is important, including when there is disagreement. Likewise, it is important that a transfer of care from the prior physician to the one providing a second opinion be enacted only if specifically requested by the patient or the physician who encouraged the second opinion.

Consults Involving Advanced Practice Providers Increasingly, specialist physicians may find themselves being consulted by nurse practitioners and physician assistants rather than other physicians. Whether the quality of the information provided to the consultant physician by these providers is different from physician-to-physician referrals has not been studied. Consulting physicians should know whether they should respond back to the advanced practice provider or to the supervising physician, if there is one. As with physician-to-physician consults, it is also important for the consultant to know whether the individual calling for the consult has an ongoing role in the care of the patient or is simply covering for a limited period of time. Finally, the consultant, if responding back to the advanced practice provider, should make sure that the information provided meets the needs of that provider and that questions are answered as they would be if responding back to another physician.

Consultation Involving Telemedicine Consultations making use of electronic health records, patient portals, and various forms of telecommunication technology, including video conferencing or cell phone communication, can improve access to care, reduce cost, and improve outcomes. This is particularly true when employed in geographic areas of health care shortage and when the clinical issues can be handled without direct contact with the patient, i.e., radiology or dermatology. However, the absence of direct contact between patient and consultant introduces special issues related to diagnostic accuracy and physician-patient relationship. Regulatory, liability, security, and confidentiality issues arise as well, as do concerns about disparities related to in access to telemedicine technologies and willingness and ability to use them among some patient populations.

479 Medical Disorders During Pregnancy

Sarah Rae Easter, Robert L. Barbieri

Each year, ~3.75 million births occur in the United States, and >130 million births occur worldwide. A significant proportion of births are complicated by medical disorders. Advances in medical care and fertility treatment have increased the number of women with serious medical problems seeking pregnancy. Medical problems that interfere with the physiologic adaptations of pregnancy increase the risk for poor pregnancy outcome. Conversely, in some instances, pregnancy events may have implications for an individual's long-term health.

HYPERTENSION

(See also Chap. 277) Cardiac output increases by 40% in pregnancy, with most of the increase due to an increase in stroke volume. Heart rate increases by ~10 beats/min during the third trimester. In the second trimester, systemic vascular resistance decreases, and this decline is associated with a fall in blood pressure. A blood pressure of ≥140/90 mmHg is abnormal and is associated with an increase in perinatal morbidity and mortality. The diagnosis of hypertension requires the measurement of two elevated blood pressures at least 4 h apart. Hypertension during pregnancy is classified as preeclampsia, gestational hypertension, or chronic hypertension. These classifications are distinguished based on timing in pregnancy and the presence of associated features (see below).

PREECLAMPSIA

Approximately 5–7% of all pregnant women develop *preeclampsia*, the new onset of hypertension (blood pressure ≥140/90 mmHg) and proteinuria (either a 24-h urinary protein >300 mg/24 h or a protein-creatinine ratio ≥0.3) after 20 weeks of gestation. Preeclampsia can be diagnosed without proteinuria in the presence of symptoms or laboratory abnormalities raising concern for end-organ damage. Specific clinical features qualify as evidence of severe disease, including severe hypertension (blood pressure ≥160/110 mmHg), new-onset symptoms (headache not responsive to medications, visual changes, unremitting severe epigastric pain, or pulmonary edema), or laboratory abnormalities signifying thrombocytopenia (platelets $<100 \times 10^9$/L), renal insufficiency (creatinine >1.1 mg/dL), or liver impairment (elevation of transaminases to twice the normal concentration). The *HELLP syndrome* (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets) is a special subtype of preeclampsia with severe features and is a major cause of morbidity and mortality. Coagulopathy, cerebrovascular accidents (CVAs), hepatic capsule rupture, and placental abruption are additional end-organ complications of preeclampsia.

The precise pathophysiology of preeclampsia remains unknown, but chronic uteroplacental ischemia, an exaggerated maternal inflammatory response, and/or imbalance of angiogenic factors likely contribute to the clinical syndrome. Excessive placental production of antagonists to both vascular endothelial growth factor (VEGF) and transforming growth factor β (TGF-β) and subsequent endothelial injury may underlie the pathophysiology in more severe presentations of the disease. Abnormalities of cerebral circulatory autoregulation explain some of the neurologic manifestations of the disease and can increase the risk of stroke at even modestly elevated blood pressures. In the absence of treatment, 1 in 200 cases of preeclampsia may progress to *eclampsia*—new-onset generalized tonic-clonic seizures in a patient with preeclampsia. Low-dose aspirin initiated between 12 and 14 weeks of gestation reduces the risk in women at high risk of developing preeclampsia.

GESTATIONAL HYPERTENSION

The development of elevated blood pressure after 20 weeks of pregnancy in the absence of preexisting chronic hypertension or proteinuria is referred to as *gestational hypertension*. Gestational hypertension with severe features of the disease is best classified as preeclampsia, whereas gestational hypertension in the absence of severe features has a similar rate of adverse outcomes to the general obstetric population.

TREATMENT

Preeclampsia

The management of preeclampsia is challenging because it requires the clinician to balance the health of the mother with the health of the fetus. The definitive treatment of preeclampsia is delivery of the fetus and placenta. This reduces the mother's morbidity but exposes the fetus to the risks of prematurity. In preeclampsia without severe features, delivery at 37 weeks is recommended. Women with preeclampsia without severe features may be managed conservatively until 37 weeks with close monitoring for development of severe features, careful fetal surveillance, and limited physical activity to reduce blood pressure.

Expectant management of preeclampsia with severe features remote from term affords some benefits for the fetus but at significant risk to the mother. For women with preeclampsia with severe features, delivery is recommended unless the patient is <34 weeks and eligible for expectant management in a tertiary hospital setting. Indications for delivery prior to 34 weeks include unremitting symptoms, development of laboratory abnormalities, or severe range blood pressures refractory to medical management. The goal of prolonging pregnancy to this gestational age is to improve neonatal outcomes. Therefore, concerns about fetal well-being, such as severe intrauterine growth restriction or placental abruption, may also prompt delivery before 34 weeks. Timely management of blood pressures >160/110 mmHg reduces the risk of CVAs. Labetalol or hydralazine IV are the first-line agents to manage severe hypertension in preeclampsia with consideration of oral agents once blood pressure is controlled. Elevated arterial pressure should be reduced slowly to avoid hypotension and a decrease in blood flow to the fetus.

Magnesium sulfate is the preferred agent to prevent eclampsia in patients with preeclampsia with severe features and for treatment and prevention of recurrent seizures in patients with eclampsia. Magnesium sulfate is administered as an IV loading dose followed by a continuous infusion, with care taken in patients with impaired renal function or pulmonary edema. Randomized trial data demonstrate that magnesium is superior to phenytoin and diazepam in reducing the risk of seizure. Women who have had preeclampsia appear to be at increased risk of cardiovascular disease later in life.

CHRONIC HYPERTENSION

Pregnancy complicated by chronic hypertension is associated with risks to mother and neonate. Pregnant women with chronic hypertension are at increased risk for superimposed preeclampsia and placental complications including intrauterine growth restriction and placental abruption. Women with chronic hypertension should have a thorough prepregnancy evaluation to identify remediable causes of hypertension and to transition off of antihypertensive agents associated with adverse outcomes in pregnancy. Labetalol and extended-release nifedipine are the most commonly used medications for the treatment of chronic hypertension in pregnancy. The target blood pressure is in the range of 130–150 mmHg systolic and 80–100 mmHg diastolic to balance maternal safety with fetal perfusion. A preconception or early pregnancy assessment for end-organ impacts of hypertension, including the presence of proteinuria, may help differentiate the effects of chronic hypertension from those of superimposed preeclampsia. There are no convincing data that the treatment of mild chronic hypertension improves perinatal outcome.

RENAL DISEASE

Normal pregnancy is characterized by an increase in glomerular filtration rate and creatinine clearance secondary to a rise in renal plasma flow and increased glomerular filtration pressures. Patients with underlying renal disease may expect a worsening of existing hypertension or development of preeclampsia during pregnancy. A prepregnancy serum creatinine level <133 μmol/L (<1.5 mg/dL) is associated with a favorable prognosis, whereas certain pathologies, such as those associated with glomerular disease, increase the risk of adverse outcomes. Neither hemodialysis nor transplant is a contraindication to pregnancy, but both require close multidisciplinary management. When renal disease worsens during pregnancy, close collaboration between the internist and the maternal-fetal medicine specialist is essential so that decisions regarding delivery can be weighed to balance the sequelae of prematurity for the neonate versus long-term sequelae for the mother with respect to future renal function.

CARDIAC DISEASE

Cardiac disease is the leading cause of maternal mortality in the United States. Prepregnancy cardiac disease and cardiac disease caused by pregnancy are both major contributors. Patient education, risk stratification, optimization of hemodynamics, and multidisciplinary planning with a pregnancy heart team are the tenets of management independent of etiology. Patients with pulmonary hypertension (Chap. 283), severe ventricular dysfunction (ejection fraction <30% or New York Heart Association class III–IV), severe mitral or aortic stenosis, severe aortic dilation, or Fontan circulation with any complication are at the highest risk of maternal mortality. Pregnancy is contraindicated in these women, with most experts recommending termination of pregnancy due to maternal risk. Risk stratification including a detailed history with attention to symptoms, echocardiography, and cardiopulmonary exercise testing guides monitoring and management for most patients. Contemporary guidelines support continuing

most nonteratogenic prepregnancy medications and reserving cesarean delivery for obstetric indications with rare exceptions.

VALVULAR HEART DISEASE

(See also Chaps. 261–268.)

Mitral Stenosis The pregnancy-induced increase in blood volume, cardiac output, and tachycardia can increase the transmitral pressure gradient and cause pulmonary edema or tachyarrhythmias in women with mitral stenosis. Women with moderate to severe mitral stenosis (mitral valve area ≤1.5 cm^2) who are planning pregnancy and have either symptomatic disease or pulmonary hypertension should undergo valvuloplasty prior to conception, preferably with percutaneous balloon valvotomy. Careful control of heart rate and avoidance of hypovolemia, especially during labor and delivery, mitigate the risk of tachycardia and reduced ventricular filling times on cardiac function. The immediate postpartum period is a time of particular concern secondary to rapid volume shifts.

Aortic Stenosis Women with aortic stenosis and a mean valve gradient <25 mmHg are likely to tolerate pregnancy. For women with symptomatic aortic stenosis or severe aortic stenosis with a peak gradient >50 mmHg, treatment before pregnancy should be considered.

Mitral and Aortic Regurgitation The pregnancy-induced decrease in systemic vascular resistance reduces the risk of cardiac failure with these conditions, especially in women with chronic lesions. As a general rule, regurgitant lesions are well tolerated in pregnancy with acute onset of mitral or aortic regurgitation as an exception.

Mechanical Heart Valves Women with mechanical heart valves are at high risk of valve thrombosis in pregnancy and warrant special consideration. Use of warfarin in pregnancy is limited to this population and still avoided in the first trimester due to its association with fetal chondrodysplasia punctate. The risk of serious neonatal bleeding and associated neurologic injury persists throughout pregnancy, but the superiority of warfarin in preventing valve thrombosis merits its use. Bridging from warfarin to heparin infusion just prior to delivery minimizes bleeding risk and facilitates neuraxial analgesia.

CONGENITAL HEART DISEASE

(See also Chap. 269) Reparative surgery has markedly increased the number of adult women with congenital heart disease seeking pregnancy with a variety of disease-specific management considerations and outcomes. Repaired septal defects are comparatively low risk, whereas unrepaired septal lesions or repaired complex lesions such as tetralogy of Fallot may warrant additional surveillance by a pregnancy heart team to ensure that pregnancy is tolerated. Women with complications in the setting of lower risk disease or with high-risk disease including uncomplicated Fontan circulation, systemic right ventricle, or cyanotic disease require delivery at a tertiary care center with subspecialty expertise. In *Eisenmenger's syndrome*, i.e., the combination of pulmonary hypertension with right-to-left shunting due to congenital abnormalities (Chap. 269), maternal and fetal deaths occur frequently, informing the recommendation for termination of pregnancy. The presence of a congenital cardiac lesion in the mother increases the risk of congenital cardiac disease in the newborn and is the basis for the recommendation to screen for fetal congenital heart disease with fetal echocardiography.

AORTOPATHY

The physiologic cardiovascular adaptations of pregnancy can predispose women to aortic dissection, with the highest risk in women with known aortic disease. Echocardiographic monitoring for evolution of the aortic root diameter is essential with consideration of complete aortic imaging with prepregnancy CT or MRI for aortic pathology in high-risk diseases. For most diseases, an aortic root diameter <40 mm portends a favorable pregnancy outcome, whereas a diameter >50 mm is an indication for prepregnancy repair. Beta blockers are a mainstay of therapy for most patients. A high clinical suspicion for dissection in patients presenting with chest pain is mandatory.

Marfan Syndrome (See also Chap. 413) This autosomal dominant disease is associated with an increased risk of aortic dissection and rupture. An aortic root diameter >40 mm is associated with an increased risk of aortic dissection, and an aortic root diameter >45 mm is an indication for surgical treatment. Operative vaginal delivery to limit the aortic wall stress associated with Valsalva should be considered for women with an aorta of 40–45 mm.

Ehlers-Danlos Syndrome (EDS) (See also Chap. 413) Type IV EDS is an autosomal dominant disease associated with an increased risk of uterine or vascular rupture that may cause death. For women with type IV or other vascular EDS, pregnancy is relatively contraindicated because of this risk.

CARDIAC COMPLICATIONS IN PREGNANCY

Arrhythmias New-onset arrhythmias in healthy patients or patients with cardiac disease are common cardiac complications. Treatment is the same as in the nonpregnant patient, and fetal tolerance of medications such as beta blockers, calcium channel blockers, and common antiarrhythmics is acceptable. Pharmacologic or electric cardioversion may be performed to improve cardiac performance and reduce symptoms according to standard indications.

Peripartum Cardiomyopathy This uncommon but life-threatening condition should be considered in patients presenting in the third trimester or postpartum period with unexplained pulmonary edema. Treatment is directed toward symptomatic relief and improvement of cardiac function. Many patients recover completely; others are left with progressive dilated cardiomyopathy. Approximately 10% of women with peripartum cardiomyopathy carry a truncating mutation in the gene encoding the titin sarcomere protein. Recurrence in a subsequent pregnancy is a risk, and women who do not have normal baseline left ventricular function after an episode of peripartum cardiomyopathy should be counseled to avoid pregnancy.

ENDOCRINE AND METABOLIC DISORDERS

The fetoplacental unit induces major metabolic changes to shunt glucose and amino acids to the fetus while the mother uses ketones and triglycerides to fuel her metabolic needs. The use of glucose by the fetus leads to a state of accelerated ketosis during maternal fasting, characterized by lower maternal glucose concentrations and higher hydroxybutyrate and acetoacetate levels. These metabolic changes are accompanied by maternal insulin resistance that increases during the course of pregnancy caused in part by placental production of steroids, a growth hormone variant, and placental lactogen.

DIABETES MELLITUS

(See also Chaps. 403–405) Pregnancy complicated by diabetes mellitus (DM) is associated with higher maternal and perinatal morbidity and mortality rates. The metabolic changes of pregnancy can precipitate hyperglycemia requiring increased insulin needs, development of diabetic ketoacidosis, or hypoglycemia. Impaired glycemic control during the critical first 5–8 weeks of pregnancy leads to the increased risk of spontaneous abortion and congenital anomalies seen in pregnancies affected by DM and highlights the importance of prepregnancy glycemic control. Pregestational DM increases the risk of stillbirth, preeclampsia, and large for gestational age infants. Macrosomia then increases the risk of shoulder dystocia and birth trauma, including brachial plexus injury and maternal lacerations. Neonates are at risk of hypoglycemia, hyperbilirubinemia, polycythemia, and respiratory distress. An assessment of end-organ complications of DM including nephropathy, retinopathy, and neuropathy is essential to understanding the patient's risk profile.

GESTATIONAL DIABETES

Gestational diabetes mellitus (GDM) occurs in ~4% of pregnancies, and screening for GDM is a routine part of prenatal care. Some advocate for screening all overweight or obese women with risk factors early in pregnancy to detect occult pregestational DM or early GDM. Regardless of early screening, the typical two-step strategy to diagnose

GDM is performed at 24–28 weeks of gestation and involves administration of a 50-g oral glucose challenge with a single serum glucose measurement at 60 min. Plasma glucose >7.2 mmol/L (>130 mg/dL) warrants administration of a 100-g oral glucose tolerance test (GTT) with plasma glucose measurements obtained in the fasting state and at 1, 2, and 3 h. Normal plasma glucose concentrations at these time points are <5.3 mmol/L (<95 mg/dL), <10 mmol/L (<180 mg/dL), <8.6 mmol/L (<155 mg/dL), and <7.8 mmol/L (<140 mg/dL) as the upper norms. Two elevated glucose values indicate a positive GTT diagnostic of GDM. Rates of adverse pregnancy outcomes demonstrate a colinear increase with increasing glucose levels challenging the optimal threshold for diagnosing GDM. GDM increases the risks of maternal and neonatal complications associated with pregestational diabetes, while treating GDM reduces the risk of preeclampsia, birth weight >400 g, and shoulder dystocia.

TREATMENT

Diabetes Mellitus in Pregnancy

Preconception counseling to optimize glycemic control and assess for end-organ complications of DM is a cost-effective and evidence-based intervention for women with DM. Guidelines encourage women considering pregnancy to initiate insulin prior to pregnancy targeting a preconception hemoglobin A_{1C} <6%. Insulin is the preferred medical therapy for pregestational DM in pregnancy due to its safety profile and lower rates of treatment failure compared to oral hypoglycemics.

Once pregnancy is established, glucose control should be managed more intensively than in the nonpregnant state with assessment of blood glucose when fasting and either 1 or 2 h after a meal at a minimum. Fasting blood glucose levels should be maintained at <5.3 mmol/L (<95 mg/dL), with postprandial targets of <7.8 mmol/L (140 mg/dL) or <6.7 mmol/L (120 mg/dL) at 1 and 2 h, respectively. Continuous glucose monitoring is an evidence-based intervention to improve neonatal outcomes in type 1 DM. Sequential measurement of hemoglobin A_{1C} is of minimal utility for monitoring glucose control during pregnancy because of the higher rate of red blood cell turnover during pregnancy and resultant falsely low values. Average daily insulin needs increase from 0.7–0.8 units/kg in the first trimester, to 0.8–1 units/kg in the second trimester, and 0.9–1.2 units/kg in the third trimester. Most management strategies utilize a combination of basal insulin with short-acting insulin at mealtime or continued use of a prepregnancy insulin pump in appropriately selected patients.

Glycemic control may become more difficult to achieve as pregnancy progresses due to an increase in insulin resistance. Attention to glycemic control and frequent fetal surveillance including ultrasounds are mainstays of management in the third trimester. Findings of a large for gestational age fetus or polyhydramnios on antenatal ultrasound can be indicators of suboptimal glycemic control. Tight glycemic control at delivery minimizes the risk of neonatal hypoglycemia due to fetal hyperinsulinemia caused by elevated maternal glucose levels. Infants of mothers with DM have higher rates of preterm birth, although preterm delivery is generally reserved for worsening maternal renal disease or active proliferative retinopathy in addition to the usual obstetric indications. Induction of labor may be recommended in the early term period of 37–39 weeks of gestation. Cesarean delivery is reserved for cases of suspected macrosomia based on an estimated fetal weight of 4500 g or greater to minimize the risk of shoulder dystocia and associated birth trauma.

Gestational Diabetes

Treatment of GDM begins with nutritional therapy to optimize normoglycemia and gestational weight gain, which is effective in the majority of women. Insulin is the preferred therapy for patients who exceed the aforementioned targets despite nutritional therapy. Metformin and glyburide are alternatives for patients who decline or cannot reliably take insulin. Contemporary data demonstrate lower mean birth weights, gestational weight gain, and rates of preeclampsia with metformin compared to both glyburide and insulin. The unknown long-term developmental and metabolic effects of metformin, including higher adiposity measurements in children exposed to metformin in utero, inform the preference for insulin.

GDM confers a 7- to 10-fold increase in the risk of developing type 2 DM later in life, with a 10% risk within 5 years of delivery. All women with GDM should have a 4- to 12-week 2-h 75-g GTT to screen for DM or impaired glucose tolerance. The increased long-term risks of DM and cardiovascular disease and the need for regular follow-up with their primary care provider should be emphasized for all women with GDM. Exercise, weight loss, and treatment with metformin reduce the risk of developing DM in these at-risk women.

OBESITY

(See also Chap. 402) Pregnant women who are obese have an increased risk GDM, preeclampsia, cesarean delivery, congenital anomalies, stillbirth, and neonatal death. A growing body of literature suggests the in utero effects of excess adipose tissue may cause changes in metabolic programming that lead to adverse health outcomes in adult life. Women contemplating pregnancy should attempt to attain a healthy weight prior to conception, recognizing that even a 10% reduction in weight may significantly reduce many of these risks. Women undergoing bariatric surgery should be counseled to avoid conception for 12–18 months after surgery until weight stabilizes. Bariatric surgery reduces the risks for some complications but requires increased laboratory surveillance for micronutrient deficiencies in pregnancy with appropriate supplementation. All women should be counseled to avoid weight gain in excess of the National Academy of Medicine guidelines (25–35 lb for normal weight, 15–25 lb for overweight, and 11–20 lb for obese women) with the knowledge that excess gestational weight gain increases the risk of macrosomia and cesarean delivery, independent of the presence of comorbid DM.

THYROID DISEASE

(See also Chap. 382) The estrogen-induced increase in thyroxine-binding globulin increases circulating levels of total T_3 and total T_4 in pregnancy. Placental human chorionic gonadotropin (hCG) directly stimulates the thyroid, causing an increase in free T_3 and T_4. Interpretation of the measurement of free T_4, free T_3, and thyroid-stimulating hormone (TSH) should use trimester-specific ranges. There are conflicting reports about a link between subclinical hypothyroidism and/or thyroid peroxidase antibodies and adverse pregnancy outcomes. Women with a history of Graves' disease have an increased risk of fetal goiter and neonatal Graves' disease independent of maternal treatment status due to the transplacental passage of maternal thyroid-stimulating antibodies and stimulation of the fetal thyroid.

TREATMENT

Hyperthyroidism

Methimazole crosses the placenta to a greater degree than propylthiouracil and has been associated with fetal aplasia cutis. However, propylthiouracil can be associated with maternal liver failure. Some experts recommend propylthiouracil in the first trimester and methimazole thereafter. Radioiodine should not be used during pregnancy, either for scanning or for treatment, because of effects on the fetal thyroid. In emergent circumstances, including thyroid storm, additional treatment with beta blockers may be necessary.

Hypothyroidism

The goal of therapy for hypothyroidism is to maintain the serum TSH in the normal range, and thyroxine is the drug of choice. The dose of thyroxine required to keep the TSH in the normal range rises during pregnancy. Since the increased thyroxine requirement occurs as early as the fifth week of pregnancy, one approach is to

increase the thyroxine dose by 30% (two additional pills weekly) as soon as pregnancy is diagnosed and then adjust the dose according to TSH.

HEMATOLOGIC DISORDERS

Pregnancy has been described as a state of physiologic anemia. Part of the reduction in hemoglobin concentration is dilutional, but iron, folate, and vitamin B_{12} deficiencies are common causes of correctable anemia during pregnancy.

Hemoglobinopathy screening with red cell indices is indicated for all pregnant women with the addition of hemoglobin electrophoresis in populations at high risk for hemoglobinopathies **(Chap. 98)** or with low mean corpuscular volume on complete blood count. Hemoglobinopathies can be associated with increased maternal and fetal morbidity and mortality, with sickle cell disease as a particularly high-risk entity in pregnancy. Management is tailored to the specific hemoglobinopathy and is generally the same for both pregnant and nonpregnant women. Prenatal diagnosis of hemoglobinopathies in the fetus is readily available and should be discussed with prospective parents either prior to or early in pregnancy.

Thrombocytopenia occurs commonly during pregnancy. The majority of cases are benign gestational thrombocytopenias, but the differential diagnosis should include immune thrombocytopenia **(Chap. 115)**, preeclampsia, and thrombotic thrombocytopenic purpura. Benign gestational thrombocytopenia is unlikely if the platelet count is <100,000/μL.

DEEP VENOUS THROMBOSIS AND PULMONARY EMBOLISM

(See also Chap. 279) Pregnancy is associated with venous stasis, endothelial injury, and a hypercoagulable state. Inherited thrombophilias and the presence of antiphospholipid antibodies increase the risk of venous thromboembolism (VTE) in pregnancy and often require prophylactic anticoagulation during pregnancy and the postpartum period to mitigate risk. Deep venous thrombosis (DVT) or pulmonary embolism (PE) occurs in about 1 in 500 pregnancies with the highest risk in the postpartum state. Physiologic edema and shortness of breath coupled with the normal elevation of D-dimer across pregnancy can make the diagnosis challenging. In general, all diagnostic and therapeutic modalities afforded to the nonpregnant patient should be utilized in pregnancy.

TREATMENT

Venous Thromboembolism

Aggressive diagnosis and management of suspected DVT or PE optimize outcomes for mother and fetus. Anticoagulant therapy with low-molecular-weight heparin (LMWH) or unfractionated heparin is indicated in pregnant women with VTE. Anticoagulants increase the risk of epidural hematoma in women receiving neuraxial analgesia in labor and must be withheld prior to placement. Prophylactic LMWH must be stopped 12 h before placement of an epidural catheter, whereas therapeutic LMWH must be withheld for a full 24 h. Transition to unfractionated heparin as delivery approaches can shorten the time between anticoagulant administration and epidural placement. The variability in achieving therapeutic levels with subcutaneous heparin may prompt peripartum transition to a heparin infusion in those at highest risk.

NEOPLASIA

Cancer complicates ~1 in 1000 pregnancies. The four cancers that occur most commonly in pregnancy are cervical cancer, breast cancer, melanoma, and lymphoma **(Table 479-1)**. In addition to cancers developing in other organs of the mother, gestational trophoblastic tumors can arise from the placenta.

Pregnancy has relatively little or no impact on the natural history of malignancies, despite the hormonal influences. Spread of the mother's cancer to the fetus (so-called vertical transmission) is exceedingly rare. However, managing cancer in a pregnant woman is complex, with competing interests for mother and fetus. Generally, the management that optimizes maternal physiology is also best for the fetus. The best way to approach management of a pregnant woman with cancer is to ask, "What would one do in this clinical situation if she was not pregnant? Then, which, if any aspect of those plans needs to be modified because she is pregnant?"

TABLE 479-1 Incidence of Malignant Tumors During Gestation

TUMOR TYPE	INCIDENCE PER 10,000 PREGNANCIES[a]	% OF CASES[b]
Breast cancer	1–3	25%
Cervical cancer	1.2–4.5	25%
Thyroid cancer	1.2	15%
Hodgkin's disease	1.6	10%
Melanoma	1–2.6	8%
Ovarian cancer	0.8	2%
All sites	10	100%

[a]These are estimates based on extrapolations from a review of >3 million pregnancies (LH Smith et al: Am J Obstet Gynecol 184:1504, 2001). [b]Based on accumulating case reports from the literature; the precision of these data is not high.

TREATMENT

Malignancy

Exposure of the developing fetus to ionizing radiation may cause adverse effects. Awareness of this potential toxicity has resulted in a disproportionate aversion to diagnostic imaging in pregnancy. The fetus is most sensitive to teratogenic agents in the first trimester during organogenesis. Imaging that uses ionizing radiation should not be done without a compelling reason and due consideration to obtaining the necessary information by alternative modalities.

Chemotherapy is associated with adverse fetal effects, but the significance of these depends on the specific agent and gestational age. Cytotoxic chemotherapy should virtually never be given in the first trimester due to risk of spontaneous abortion or malformation. If avoiding chemotherapy during this vulnerable time period could compromise maternal health, patients should be counseled about the role of therapeutic abortion to avoid serious neonatal sequelae.

A variety of single agents and combinations have been administered in the second and third trimesters, without a high frequency of toxic effects to the pregnancy or the fetus. Whether the association between chemotherapy and outcomes such as fetal growth restriction is due to the therapy or underlying malignancy is unknown. Literature supporting the short- and long-term neonatal safety of common agents is growing. For malignancies diagnosed closer to term or slowly progressive malignancies, delaying treatment until after delivery to avoid fetal exposure to chemotherapy may be desirable. If delaying therapy may compromise maternal prognosis and the patient is beyond the first trimester, then treatment might be initiated in pregnancy with plans to deliver the fetus preterm to avoid excess exposure to chemotherapy. Neonatal prognosis is most closely linked to gestational age at delivery. Decisions regarding timing of delivery should contextualize this within the natural history of the disease and safety of the proposed treatment.

NEUROLOGIC DISORDERS

Neurologic complaints such as headaches or neuropathies are common in pregnancy, and differentiating bothersome symptoms from life-threatening pathology is challenging. While most complaints are benign, *cerebrovascular accidents* (CVAs) should be high on the differential diagnosis and evaluated with noncontrast head CT in cases of suspected stroke. Less acute neurologic complaints are optimally evaluated with noncontrast MRI. The increased prevalence of cerebral venous thrombosis and arterial dissection may require additional imaging with magnetic resonance venography or arteriography, respectively, remembering that gadolinium should be avoided in pregnancy.

Exclusion of preeclampsia is important for any patient presenting with a headache after 20 weeks of gestation with a low threshold to assess for CVA due to the comparatively high prevalence in this population. Headache in preeclampsia can be associated with the *posterior reversible encephalopathy syndrome* (PRES), which is on the spectrum of *reversible cerebral vasoconstriction syndromes* (RCVS) that can present in pregnancy with neurologic complaints. Peripheral nerve disorders associated with pregnancy include *Bell's palsy* (idiopathic facial paralysis) **(Chap. 446)**, *carpal tunnel syndrome* (median nerve entrapment), or *meralgia paresthetica* (lateral femoral cutaneous nerve entrapment). *Restless leg syndrome* is the most common peripheral nerve and movement disorder in pregnancy, and complaints should prompt an evaluation for disordered iron metabolism.

Pregnancy is safe for the majority of women with neurologic disorders with management considerations focusing on medication safety, the impact of pregnancy on the disease, and potential neonatal consequences. For women with *epilepsy* planning pregnancy, lamotrigine and levetiracetam are first-line monotherapies due to the wealth of safety data. The decision to change antiepileptic drugs (AEDs) for pregnancy should be individualized, with avoidance of valproate due to known risk of congenital malformations. Folic acid supplementation of 4 mg daily should be considered in women taking AEDs. Escalating doses of AEDs may be required due to increased clearance in pregnancy and guided by monthly monitoring of AED levels.

Patients with preexisting *multiple sclerosis* **(Chap. 444)** experience a gradual decrease in the risk of relapses as pregnancy progresses and, conversely, an increase in attack risk during the postpartum period. Disease-modifying agents should be withheld in pregnancy, and relapses should be treated with glucocorticoids. Finally, certain tumors, particularly pituitary adenoma and meningioma **(Chap. 380)**, may manifest during pregnancy because of accelerated growth, possibly driven by hormonal factors. Neuroimaging with noncontrast MRI may be required for women with a history of tumors to facilitate neuraxial analgesia.

GASTROINTESTINAL AND LIVER DISEASE

Up to 90% of pregnant women experience nausea and vomiting during the first trimester of pregnancy. *Hyperemesis gravidarum* is a severe form that prevents adequate fluid and nutritional intake and may require hospitalization to prevent dehydration and malnutrition. Thiamine and folate supplementation and monitoring of electrolytes for evidence of refeeding syndrome should be considered in severe cases with evaluation for supplemental enteral nutrition in refractory disease.

Exacerbation of *inflammatory bowel disease* is common, and medical management of these conditions parallels the nonpregnant state **(Chap. 326)**. Pregnancy is a risk factor for development or worsening of gallbladder disease such as cholelithiasis. This aggravation may be due to pregnancy-induced alteration in the metabolism of bile and fatty acids. *Intrahepatic cholestasis of pregnancy* is generally a third-trimester event presenting with profound pruritis and confirmed with an elevated level of bile acids with or without transaminitis. The association between cholestasis and stillbirth merits increased fetal surveillance and delivery by 37 weeks of gestation. Symptoms can be improved with the use of ursodiol.

Acute fatty liver is a rare complication of pregnancy on the spectrum with HELLP syndrome and preeclampsia. Acute fatty liver of pregnancy is generally distinguished by markedly increased serum levels of bilirubin and ammonia and by hypoglycemia. Management of acute fatty liver of pregnancy includes delivery accompanied by supportive care.

All pregnant women should be screened for *hepatitis B virus* and *hepatitis C virus*. All infants receive hepatitis B vaccine, but infants born to mothers who are carriers of hepatitis B surface antigen should also receive hepatitis B immune globulin as soon after birth as possible to decrease the risk of vertical transmission. The presence of the hepatitis B E antigen in the mother and high viral load increase this risk. Strategies to decrease vertical transmission of hepatitis C are limited to avoiding procedures (i.e., amniocentesis) that increase the risk. Postpartum referral to a specialist for consideration of potentially curative therapy is indicated.

INFECTIONS

BACTERIAL INFECTIONS

All pregnant patients are screened prenatally for syphilis, gonorrhea, and chlamydial infections, and the detection of any of these should result in prompt evaluation and treatment **(Chaps. 156 and 189)**. Other than *bacterial vaginosis*, the most common bacterial infections during pregnancy involve the urinary tract **(Chap. 135)**. All pregnant women should be screened with a urine culture for *asymptomatic bacteriuria* at the first prenatal visit. Pregnancy is an indication for treatment of asymptomatic bacteriuria to avoid pyelonephritis. Progesterone-mediated ureteral and bladder smooth muscle relaxation, coupled with compression effects of the enlarging uterus, promote stasis and increase the risk of these conditions. Pregnant women who develop pyelonephritis should be treated with inpatient IV antibiotic administration due to the elevated risk of urosepsis and acute respiratory distress syndrome in pregnancy-associated pyelonephritis. Pregnant women with recurrent urinary tract infections or one episode of pyelonephritis should be considered for daily antibiotic suppressive treatment throughout the remainder of their pregnancy.

VIRAL INFECTIONS

All pregnant women should be screened for hepatitis B virus, hepatitis C virus, and HIV. In addition, all pregnant women should be screened for immunity to rubella and varicella.

Influenza **(See also Chap. 200)** Pregnant women with influenza are at increased risk of serious complications and death. All women who are pregnant or plan to become pregnant in the near future should receive inactivated influenza vaccine. The prompt initiation of antiviral treatment is recommended for pregnant women in whom influenza is suspected. Treatment can be reconsidered once the results of high-sensitivity tests are available. Prompt initiation of treatment lowers the risk of admission to an intensive care unit and death.

Cytomegalovirus Infection The most common cause of congenital viral infection in the United States is cytomegalovirus (CMV) **(Chap. 195)**. As many as 50–90% of women of childbearing age have antibodies to CMV, but only rarely does CMV reactivation result in neonatal infection. More commonly, primary CMV infection during pregnancy creates a risk of congenital CMV. No currently accepted treatment of CMV infection during pregnancy has been demonstrated to protect the fetus effectively. Severe CMV disease in the newborn is characterized most often by petechiae, hepatosplenomegaly, and jaundice. Chorioretinitis, microcephaly, intracranial calcifications, hepatitis, hemolytic anemia, and purpura may also develop. Central nervous system (CNS) involvement can result in the development of psychomotor, ocular, auditory, and dental abnormalities over time. Women with a primary CMV infection should delay conception for 6 months.

Herpesvirus Infection **(See also Chap. 192)** The acquisition of genital herpes during pregnancy is associated with spontaneous abortion, prematurity, and congenital and neonatal herpes. Disseminated neonatal herpes carries with it high mortality and morbidity rates from CNS involvement. A cohort study of pregnant women without evidence of previous herpesvirus infection demonstrated that ~2% acquired a new herpesvirus infection during the pregnancy and ~60% of the newly infected women had no clinical symptoms. The risk of transmission was increased in those with infections closer to delivery. The risk of active genital herpes lesions at term can be reduced by prescribing acyclovir for the last 4 weeks of pregnancy to all women who had an episode of genital herpes during the pregnancy. Pregnant women with active genital herpes lesions at the time of presentation in labor should be delivered by cesarean section.

Rubella **(See also Chap. 206)** Rubella virus is a known teratogen; first-trimester rubella carries a high risk of fetal anomalies, though the risk significantly decreases later in pregnancy. Congenital rubella

may be diagnosed by percutaneous umbilical-blood sampling with the detection of IgM antibodies in fetal blood. All pregnant women and all women of childbearing age should be tested for their immune status to rubella.

Parvovirus Infection (See also Chap. 197) Infection with human parvovirus B19 may occur during pregnancy. It rarely causes sequelae, but nonimmune women infected during pregnancy may be at risk for fetal hydrops secondary to erythroid aplasia and profound anemia. Management includes screening for fetal anemia with Doppler assessment of the middle cerebral artery and consideration of intrauterine transfusion of red blood cells to the fetus to avoid the physiologic consequences of anemia while awaiting fetal recovery.

HIV Infection (See also Chap. 202) The predominant cause of HIV infection in children is transmission of the virus from mother to newborn during the perinatal period. All pregnant women should be screened for HIV infection. Factors that increase the risk of mother-to-newborn transmission include high maternal viral load, low maternal CD4+ T-cell count, prolonged labor, prolonged duration of membrane rupture, and the presence of other genital tract infections, such as syphilis or herpes. Antiretroviral therapy (ART) has decreased the rate of perinatal transmission from 20% to ~1%. For women receiving antepartum ART, maternal viral load guides the decision for vaginal versus cesarean delivery and need for adjunct intrapartum zidovudine. Women with an undetectable viral load are at the lowest risk of transmission and require no additional therapy. Those without antepartum ART exposure or with viral loads >1000 copies/mL at delivery require IV zidovudine and a prelabor cesarean delivery, typically scheduled at 38 weeks. Cesarean delivery should be reserved for obstetric indications for women with ≥50 but ≤1000 copies/mL, and intrapartum zidovudine can be considered.

Zika Virus Zika virus (ZV) can be transmitted from mother to fetus throughout gestation and often results in fetal death, severe microcephaly, or other malformations of the CNS. Pregnant symptomatic women with relevant epidemiologic exposure within 2 weeks of symptom onset should have serum and urine tested for ZV ribonucleic acid by real-time reverse transcriptase polymerase chain reaction (RT-PCR). Testing 2–12 weeks after symptom onset utilizes serum measurement of Zika and dengue virus IgM. Sequential obstetrical ultrasound is recommended to assess for fetal growth and anomalies. Couples considering pregnancy should avoid travel to areas with known mosquito transmission of ZV.

VACCINATIONS

(See also Chap. 123) For rubella-nonimmune individuals contemplating pregnancy, measles-mumps-rubella vaccine should be administered, ideally at least 3 months prior to conception, but otherwise in the immediate postpartum period. All pregnant women should be vaccinated against influenza. Administration of one dose of the tetanus, diphtheria, and pertussis (Tdap) vaccine between 27 and 36 weeks of gestation is recommended to promote maternal IgG production and reduce the risk of neonatal pertussis due to transplacental passage of IgG.

MATERNAL MORTALITY

Maternal death is defined as death occurring during pregnancy or within 42 days of completion of pregnancy from a cause related to or aggravated by pregnancy, but not due to accident or incidental causes. The maternal mortality ratio is the number of maternal deaths per 100,000 live births. From 1935 to 2007, the U.S. maternal mortality ratio decreased from nearly 600/100,000 births to 12.7/100,000 births. Changes in reporting prohibited publication of a maternal mortality ratio for >10 years until the 2020 release of the 2018 maternal mortality ratio of 17.4/100,000 births. An increasingly complex patient population, in addition to changes in measurement, likely contributed to this rise in maternal death. There are significant racial and ethnic disparities in the maternal mortality ratio, with a nearly fourfold increased risk of death for non-Hispanic black women compared to non-Hispanic white women (37.1 vs 14.7 deaths per 100,000 live births, respectively) (Chap. 10).

Updated data on the causes of maternal death in the new reporting framework are forthcoming, but extrapolating evidence from causes of pregnancy-related death is enlightening. Pregnancy-related death is defined as the death of a woman while pregnant or within 1 year of the end of pregnancy from any cause related to or aggravated by pregnancy. Cardiovascular disease, including cardiomyopathy, accounted for nearly a third of pregnancy-related deaths from 2014 to 2017 followed by infection, noncardiovascular medical conditions, hemorrhage, and thrombotic events. The relative contribution of medical disease to pregnancy-related death, coupled with knowledge that one in three pregnancy-related deaths occur 1 week to 1 year after delivery, highlights the role of the specialist in internal medicine in reducing maternal mortality.

In some countries in sub-Saharan Africa and southern Asia, the maternal mortality ratio is >500/100,000 live births. The most common causes of maternal death in these countries are maternal hemorrhage, hypertensive disorders, infection, obstructed labor, and complications from unsafe pregnancy termination. The health interventions that would have the greatest impact on maternal health include improving the following components of the health system: (1) access to contraceptive services in order to space births and limit total family size; (2) access to safe pregnancy termination; (3) presence of trained birth attendants at all deliveries; and (4) transportation to emergency obstetrical centers that can provide intensive medical and surgical services, including cesarean delivery. Maternal death is a global public health tragedy that could be mitigated with the application of modest resources.

SUMMARY

With improved diagnostic and therapeutic modalities as well as advances in the treatment of infertility, more patients with serious medical complications will be seeking to become pregnant and will require complex obstetric care. Improved outcomes of pregnancy in these women will be best attained by a team of internists, maternal-fetal medicine (high-risk obstetrics) specialists, pediatricians, and anesthesiologists assembled to counsel these patients about the risks of pregnancy and to plan their treatment prior to, and following, conception. The importance of preconception counseling and the impact of events of pregnancy on lifelong disease cannot be overstated. It is the responsibility of all physicians caring for women in the reproductive age group to assess their patients' reproductive plans as part of their overall health evaluation.

480 Medical Evaluation of the Surgical Patient

Prashant Vaishnava, Kim A. Eagle

Cardiovascular and pulmonary complications continue to account for major morbidity and mortality in patients undergoing noncardiac surgery. Emerging evidence-based practices dictate that the internist should perform an individualized evaluation of the surgical patient to provide an accurate preoperative risk assessment and stratification that will guide optimal perioperative risk-reduction strategies. This chapter reviews cardiovascular and pulmonary preoperative risk assessment, emphasizing the goal-directed management of patients at elevated risk for adverse cardiovascular outcomes in the perioperative period. In addition, perioperative management of diabetes mellitus and prophylaxis of endocarditis and for venous thromboembolism are reviewed.

EVALUATION OF INTERMEDIATE- AND HIGH-RISK PATIENTS

Simple, standardized preoperative screening questionnaires, such as the one shown in **Table 480-1**, have been developed for the purpose of identifying patients at intermediate or high risk who may benefit from a more detailed clinical evaluation. Evaluation of such patients for surgery should always begin with a thorough history and physical examination and with a 12-lead resting electrocardiogram, in accordance with the American College of Cardiology/American Heart Association guidelines. The history should focus on symptoms of occult cardiac or pulmonary disease. The urgency of the surgery should be determined, as true emergency procedures are associated with unavoidably higher morbidity and mortality risk. Preoperative laboratory testing should be carried out only for specific clinical conditions, as noted during clinical examination. Thus, healthy patients of any age who are undergoing elective surgical procedures without coexisting medical conditions should not require any testing unless the degree of surgical stress may result in unusual changes from the baseline state.

TABLE 480-1 Standardized Preoperative Questionnaire[a]

1. Age, weight, height
2. Are you:
   Female and 55 years of age or older or male and 45 years of age or older?
   If yes, are you 70 years of age or older?
3. Do you take anticoagulant medications ("blood thinners")?
4. Do you have or have you had any of the following heart-related conditions?
   Heart disease
   Heart attack within the last 6 months
   Angina (chest pain)
   Irregular heartbeat
   Heart failure
5. Do you have or have you ever had any of the following?
   Rheumatoid arthritis
   Kidney disease
   Liver disease
   Diabetes
6. Do you get short of breath when you lie flat?
7. Are you currently on oxygen treatment?
8. Do you have a chronic cough that produces any discharge or fluid?
9. Do you have lung problems or diseases?
10. Have you or any blood member of your family ever had a problem other than nausea with any anesthesia?
    If yes, describe:
11. If female, is it possible that you are pregnant?
    Pregnancy test:
    Please list date of last menstrual period:

[a]University of Michigan Health System patient information report. Patients who answer yes to any of questions 2–9 should receive a more detailed clinical evaluation.

PREOPERATIVE CARDIAC RISK ASSESSMENT

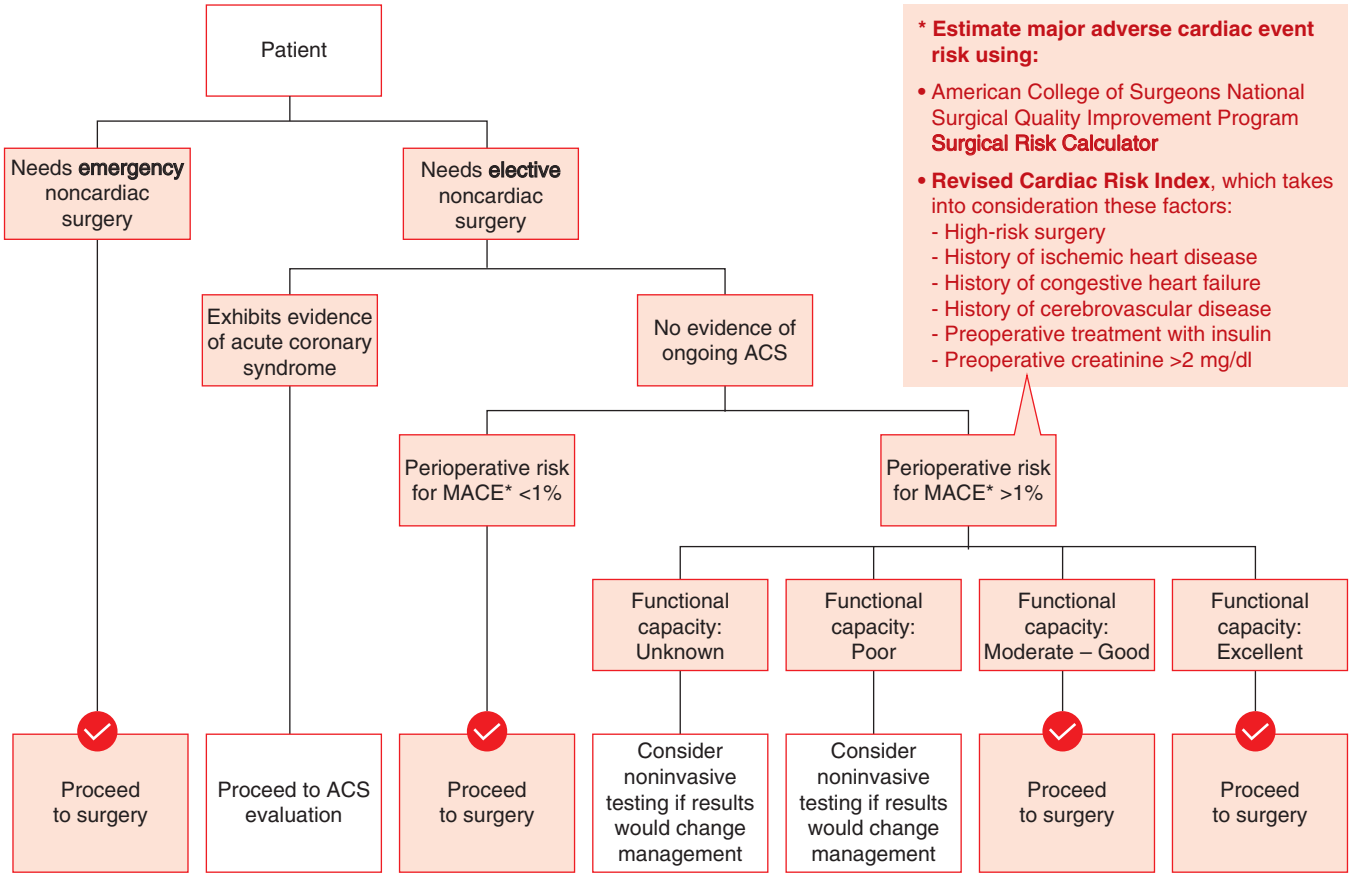
A stepwise approach to cardiac risk assessment and stratification in patients undergoing noncardiac surgery is illustrated in **Fig. 480-1**. The evaluation begins with characterization of the combined surgical and clinical risk into categories of low (<1%) and elevated risk for major adverse cardiovascular events (MACEs). Select surgeries are associated with very low risk for MACE; these surgeries and procedures include select ophthalmologic surgeries (e.g., cataract surgery), select endoscopic procedures, and select superficial procedures. Patients undergoing these low-risk procedures should proceed to surgery without further testing. Clinical risk may be estimated with the American College of Surgeons' National Surgical Quality Improvement Program (NSQIP) risk calculator (*http://www.riskcalculator.facs.org*) or with calculation of the Revised Cardiac Risk Index (RCRI).

Previous studies have compared several cardiac risk indices. The American College of Surgeons' NSQIP prospective database has identified five predictors of perioperative myocardial infarction (MI) and cardiac arrest based on increasing age, American Society of Anesthesiologists class, type of surgery, dependent functional status, and abnormal serum creatinine level. However, given its accuracy and simplicity, the RCRI **(Table 480-2)** is often the favored risk index. The RCRI relies on the presence or absence of six identifiable predictive factors: high-risk surgery, ischemic heart disease, congestive heart failure, cerebrovascular disease, diabetes mellitus treated with insulin, and renal insufficiency with a creatinine >2.0 mg/dL. Each of these predictors is assigned one point. The risk of major cardiac events—defined as MI, pulmonary edema, ventricular fibrillation or primary cardiac arrest, and complete heart block—can then be predicted. Based on the presence of none, one, two, three, or more of these clinical predictors, the rate of development of one of these four major cardiac events is estimated to be 0.4%, 0.9%, 7%, and 11%, respectively **(Fig. 480-2)**. The clinical utility of the RCRI is to identify patients with three or more predictors who are at very high risk (≥11%) for cardiac complications and who may benefit from further risk stratification with noninvasive cardiac testing, initiation of preoperative preventive medical management, or avoidance of surgery.

For patients at elevated combined clinical and surgical risk for MACE, the stepwise perioperative cardiac assessment for coronary artery disease (CAD) proceeds with consideration of functional capacity. Participation in activities of daily living offers an expression of functional capacity, often expressed in terms of metabolic equivalents (METs). For predicting perioperative events, poor exercise tolerance has been defined as the inability to walk four blocks or climb two flights of stairs at a normal pace or to meet a MET level of 4 (e.g., carrying objects of 15–20 lb. or playing golf or doubles tennis) because of the development of dyspnea, angina, or excessive fatigue **(Table 480-3)**. Patients with moderate or greater (≥4 METs) functional capacity (e.g., climbing up a flight of stairs, walking up a hill, or walking on level ground at 4 mph) generally should not undergo further noninvasive cardiac testing prior to elective noncardiac surgery. Those patients with poor (<4 METs) or unknown functional capacity should undergo pharmacological stress testing if the results of such testing would impact decision-making or perioperative care.

PREOPERATIVE NONINVASIVE CARDIAC TESTING FOR RISK STRATIFICATION

There is little evidence to support widespread application of preoperative noninvasive cardiac testing for all patients undergoing major surgery. The current paradigm to guide the need for noninvasive cardiac testing is to perform such testing in patients with poor or



PERIOPERATIVE MEDICAL INTERVENTION WHEN CONSIDERING NONCARDIAC SURGERY

Beta-blockers	Statin	Alpha agonist	ACE inhibitor	Aspirin
• Start in intermediate- to high-risk patients • Should not start on day of surgery • Should not be withdrawn if taking chronically	• Continued if on chronically • Start in vascular surgery patients • Considered in patients with clinical indications, undergoing elevated-risk procedures	Initiation not recommended prior to noncardiac surgery	Continued, or if held before surgery, restart postoperatively as soon as clinically feasible	Continued when the risk of increased cardiac events outweighs the risk of increased bleeding

FIGURE 480-1 Composite algorithm for cardiac risk assessment and stratification in patients undergoing noncardiac surgery. Preoperative evaluation involves a stepwise clinical evaluation. Those individuals requiring emergency surgery should proceed without further risk stratification. Acute coronary syndrome (step 2) should be evaluated and treated, accordingly to goal-directed medical therapy. For patients awaiting nonemergent surgeries and without acute coronary syndrome, perioperative risk is a combination of clinical and surgical risk. Select procedures and surgeries (e.g., select endoscopic procedures) are associated with low (<1%) perioperative risk and no further clinical testing is generally necessary. For those procedures associated with elevated risk, an assessment of functional capacity informs the decision for further testing. Those individuals with moderate or greater functional capacity do not require further testing and should proceed to surgery. Individuals with poor or unknown functional capacity may require pharmacologic stress testing if it would change decision-making or perioperative care. *(Reproduced with permission from AY Patel et al: Cardiac risk of noncardiac surgery. J Am Coll Cardiol 66:2140, 2015.)*

unknown capacity if it would alter clinical management or modify perioperative care. Options for pharmacological stress testing include dobutamine stress echocardiography or myocardial perfusion imaging with coronary vasodilator stress (dipyridamole, adenosine, or regadenoson) with thallium-201 and/or technetium-99m. Routine screening with noninvasive stress testing is not recommended in patients at low risk for noncardiac surgery. Furthermore, coronary revascularization before noncardiac surgery is not recommended for the express purpose of reducing perioperative cardiac events. That said, revascularization before noncardiac surgery should be considered in patients if it would be indicated regardless of the surgery planned and instead according to clinical practice guidelines. In the Coronary Artery Revascular Prophylaxis trial, there were no differences in perioperative and long-term cardiac outcomes with or without preoperative coronary revascularization; of note, patients with left main disease were excluded.

RISK MODIFICATION: PREVENTIVE STRATEGIES TO REDUCE CARDIAC RISK

Perioperative Coronary Revascularization *Prophylactic* coronary revascularization with either coronary artery bypass grafting (CABG) or percutaneous coronary intervention (PCI) provides no short- or mid-term survival benefit for patients *without* left main CAD or three-vessel CAD in the presence of poor left ventricular systolic function and is *not recommended* for patients with stable CAD before noncardiac surgery. Although PCI is associated with lower procedural risk than is CABG in the perioperative setting, the placement of a coronary artery stent soon before noncardiac surgery may increase the risk of bleeding during surgery if dual antiplatelet therapy (DAPT) (aspirin and $P2Y_{12}$) is administered; moreover, stent placement shortly before noncardiac surgery increases the perioperative risk of MI and cardiac death due to stent thrombosis if such therapy is withdrawn prematurely

TABLE 480-2 Clinical Markers Included in the Revised Cardiac Risk Index

High-Risk Surgical Procedures
Vascular surgery (except carotid endarterectomy)
Major intraperitoneal or intrathoracic procedures
Ischemic Heart Disease
History of myocardial infarction
Current angina considered to be ischemic
Requirement for sublingual nitroglycerin
Positive exercise test
Pathological Q-waves on ECG
History of PCI and/or CABG with current angina considered to be ischemic
Congestive Heart Failure
Left ventricular failure by physical examination
History of paroxysmal nocturnal dyspnea
History of pulmonary edema
S_3 gallop on cardiac auscultation
Bilateral rales on pulmonary auscultation
Pulmonary edema on chest x-ray
Cerebrovascular Disease
History of transient ischemic attack
History of cerebrovascular accident
Diabetes Mellitus
Treatment with insulin
Chronic Renal Insufficiency
Serum creatinine >2 mg/dL

Abbreviations: CABG, coronary artery bypass grafting; ECG, electrocardiogram; PCI, percutaneous coronary intervention.

(Chap. 276). It is recommended that, if possible, elective noncardiac surgery be delayed 30 days after placement of a bare metal intracoronary stent and ideally for 6 months after deployment of a drug-eluting stent (DES). Contemporary stent platforms allow for greater flexibility in the earlier interruption of DAPT; current clinical practice guidelines do suggest consideration of elective noncardiac surgery 6 months after DES implantation if the risk of further delaying surgery exceeds the risk of stent thrombosis/myocardial ischemia. For patients who *must* undergo noncardiac surgery early (>14 days) after PCI, balloon angioplasty without stent placement appears to be a reasonable alternative because DAPT is not necessary in such patients.

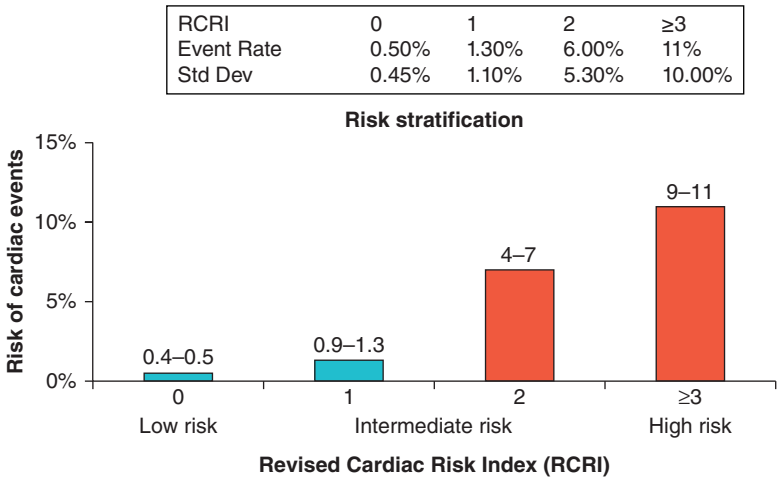

FIGURE 480-2 Risk stratification based on the Revised Cardiac Risk Index; derivation and prospective validation of a simple index for prediction of cardiac risk in patients undergoing major noncardiac surgery. Cardiac events include myocardial infarction, pulmonary edema, ventricular fibrillation, cardiac asystole, and complete heart block. *(Adapted from TH Lee et al: Circulation 100:1043, 1999.)*

PERIOPERATIVE PREVENTIVE MEDICAL THERAPIES The goal of perioperative preventive medical therapies with β-adrenergic antagonists, hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins), and antiplatelet agents is to reduce perioperative adrenergic stimulation, ischemia, and inflammation, all of which are heightened during the perioperative period.

B-ADRENERGIC ANTAGONISTS The use of perioperative beta blockade should be based on a thorough assessment of a patient's perioperative clinical and surgery-specific cardiac risk (e.g., as with the RCRI). The paradigm for beta blockade in the perioperative period has shifted in recent years owing, firstly, to the publication of the PeriOperative Ischemic Evaluation (POISE) trial demonstrating that, while perioperative beta blockade reduces the perioperative risk for MI, this is at the expense of increased death and stroke. Regarding POISE, this trial has been criticized for the use of an excessive dose of beta blocker in the perioperative period and one that may not be reflective of clinical practice, nor one that was titrated in the days or weeks preceding the procedure or surgery. Secondly, research misconduct has discredited the Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echocardiography (DECREASE) family of studies, which previously contributed to the bedrock of data supporting the use of perioperative beta blockade but have now been retracted.

Current guidelines emphasize the following key points:

1. Continuation of beta blockade in patients undergoing surgery and who have been receiving such therapy chronically.
2. Avoidance of beta-blocker withdrawal or initiation on the day of surgery.
3. Consideration of initiation of beta-blocker therapy perioperatively (ideally far enough in advance to assess safety and tolerability) in very select high-risk patients, namely, those with intermediate- or high-risk ischemia or three or more RCRI risk factors.

HMG-COA REDUCTASE INHIBITORS (STATINS) A number of prospective and retrospective studies support the perioperative prophylactic use of statins for reduction of cardiac complications in patients with established atherosclerosis. For patients undergoing noncardiac surgery and currently taking statins, statin therapy *should be continued* to reduce perioperative cardiac risk. Initiation of statin therapy is *reasonable* for patients undergoing vascular surgery independent of clinical risk. Perioperative initiation of statin therapy should be considered in patients undergoing elevated-risk procedures if there is an indication for such therapy separate from the surgery and according to clinical practice guidelines.

ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITORS It is important to maintain continuity of therapy with ACE inhibitors (when such therapy is used for the treatment of heart failure or hypertension).

ORAL ANTIPLATELET AGENTS The 4- to 6-week period following implantation of an intracoronary stent (bare metal or drug eluting) constitutes the period of time of greatest risk for the development of stent thrombosis. If possible,

noncardiac surgery should be avoided in this vulnerable period. The duration of DAPT thereafter is dictated by the circumstances in which PCI was performed and whether the indication was stable ischemic heart disease or acute coronary syndrome. For the former among patients treated with a DES, DAPT should be given for at least 6 months. For the latter, DAPT should be given for at least 12 months. However, DAPT may be interrupted to allow for noncardiac surgery 30 days after BMS and 6 months after DES, respectively. Elective, noncardiac surgery should be delayed for 5 days since the last dose of clopidogrel; 7 days since the last dose of prasugrel; and 3–5 days since the last dose of ticagrelor. The use of cangrelor, an intravenous reversible $P2Y_{12}$ receptor antagonist, may be an appealing bridging strategy (with an infusion given at a bridging dose of 0.75 μg/kg per min, although studies of its use in those undergoing cardiac and noncardiac surgery are limited. If $P2Y_{12}$ inhibitor therapy (clopidogrel, prasugrel, or ticagrelor) is interrupted or discontinued in patients who have received intracoronary stents, aspirin should be continued perioperatively (save select circumstances where the risk of bleeding may be catastrophic as in neurosurgical or spinal procedures) and the $P2Y_{12}$ receptor inhibitor should be restarted as soon as possible postoperatively. Decisions surrounding antiplatelet management in the perioperative setting among patients who have received intracoronary stents are complex and should involve multidisciplinary decision-making.

A_2 AGONISTS Based on the results of POISE-2 (a large multicenter, international, blinded randomized clinical trial of aspirin and clonidine), α_2 agonists for prevention of cardiac events are not recommended in patients who are undergoing noncardiac surgery. In this trial, clonidine increased the rate of nonfatal cardiac arrest and clinically important hypotension, while reducing the rate of death or nonfatal MI.

CALCIUM CHANNEL BLOCKERS Evidence is lacking to support the use of calcium channel blockers as a prophylactic strategy to decrease perioperative risk in major noncardiac surgery.

ANESTHETICS Mortality risk is low with safe delivery of modern anesthesia, especially among low-risk patients undergoing low-risk surgery (Table 480-4). Inhaled anesthetics have predictable circulatory and respiratory effects: all decrease arterial pressure in a dose-dependent manner by reducing sympathetic tone and causing systemic vasodilation, myocardial depression, and decreased cardiac output. Inhaled anesthetics also cause respiratory depression, with diminished responses to both hypercapnia and hypoxemia, in a dose-dependent manner; in addition, these agents have a variable effect on heart rate. Prolonged residual neuromuscular blockade also increases the risk of postoperative pulmonary complications due to reduction in functional residual lung capacity, loss of diaphragmatic and intercostal muscle function, atelectasis, and arterial hypoxemia from ventilation–perfusion mismatch.

Several meta-analyses have shown that rates of pneumonia and respiratory failure are lower among patients receiving neuroaxial anesthesia (epidural or spinal) rather than general anesthesia. However, there were no significant differences in cardiac events between the two approaches. Evidence from a meta-analysis of randomized controlled trials supports postoperative epidural analgesia for >24 h for the purpose of pain relief. However, the risk of epidural hematoma in the setting of systemic anticoagulation for venous thromboembolism prophylaxis (see below) and postoperative epidural catheterization must be considered.

TABLE 480-4 Gradation of Mortality Risk of Common Noncardiac Surgical Procedures

Higher	• Emergent major operations, especially in the elderly • Aortic and other noncarotid major vascular surgery (endovascular and nonendovascular) • Prolonged surgery associated with large fluid shift and/or blood loss
Intermediate	• Major thoracic surgery • Major abdominal surgery • Carotid endarterectomy surgery • Head/neck surgery • Orthopedic surgery • Prostate surgery
Lower	• Eye, skin, and superficial surgery • Endoscopic procedures

PREOPERATIVE PULMONARY RISK ASSESSMENT

Perioperative pulmonary complications occur frequently and lead to significant morbidity and mortality. Clinical practice guidelines recommend the following:

1. All patients undergoing noncardiac surgery should be assessed for risk of pulmonary complications (Table 480-5).
2. While select studies have suggested that quitting smoking shortly before surgery increases the risk for postoperative complications through increased sputum production and/or decreased cough, meta-analysis of the available data has challenged this, and all patients should be advised of the imperative to stop smoking presurgically.
3. Patients undergoing emergency or prolonged (3–4 h) surgery; aortic aneurysm repair; vascular surgery; major abdominal, thoracic, neurologic, head, or neck surgery; and general anesthesia should be considered to be at elevated risk for postoperative pulmonary complications.
4. Patients at higher risk of pulmonary complications should undergo incentive spirometry, deep breathing exercises, cough encouragement, postural drainage, percussion and vibration, suctioning and ambulation, intermittent positive-pressure breathing, continuous positive airway pressure, and selective use of a nasogastric tube for postoperative nausea, vomiting, or symptomatic abdominal distention to reduce postoperative risk. Multiple pulmonary risk indices are available to estimate the postoperative risk of respiratory failure, pneumonia, and other pulmonary complications; among these is the ARISCAT risk index, which accounts for the following seven risk factors: age, low preoperative oxygen saturation, respiratory infection within the preceding month, upper abdominal or thoracic surgery, surgery lasting >2 h, hemoglobin <10 g/dL, and emergency surgery (Table 480-6).

TABLE 480-5 Predisposing Risk Factors for Pulmonary Complications

1. Upper respiratory tract infection: cough, dyspnea
2. Age >60 years
3. Chronic obstructive pulmonary disease
4. Cigarette use
5. American Society of Anesthesiologists Class ≥2
6. Functional dependence
7. Congestive heart failure
8. Serum albumin <3.5 g/dL
9. Obstructive sleep apnea
10. Impaired sensorium (confusion, delirium, or mental status changes)
11. Abnormal findings on chest examination
12. Alcohol use
13. Weight loss
14. Spirometry threshold before lung resection
    a. FEV_1 <2 L
    b. MVV <50% of predicted
    c. PEF <100 L or 50% predicted value
    d. PCO_2 ≥45 mmHg
    e. PO_2 ≤50 mmHg

Abbreviations: FEV_1, forced expiratory volume in 1 s; MVV, maximal voluntary ventilation; PCO_2, partial pressure of carbon dioxide; PEF, peak expiratory flow rate; PO_2, partial pressure of oxygen.

TABLE 480-6 Risk Modification to Reduce Perioperative Pulmonary Complications

Preoperatively
• Smoking cessation
• Training in proper lung expansion techniques
• Inhalation bronchodilator and/or steroid therapy, when indicated
• Control of infection and secretion, when indicated
• Weight reduction, when appropriate
Intraoperatively
• Limited duration of anesthesia
• Avoidance of long-acting neuromuscular blocking drugs, when indicated
• Prevention of aspiration and maintenance of optimal bronchodilation
Postoperatively
• Optimization of inspiratory capacity maneuvers, with attention to:
• Mobilization of secretions
• Early ambulation
• Encouragement of coughing
• Selective use of a nasogastric tube
• Adequate pain control without excessive narcotics

Source: From VA Lawrence et al: Ann Intern Med 144:596, 2006, and WF Dunn, PD Scanlon: Mayo Clin Proc 68:371, 1993.

5. Preoperative spirometry and chest radiography should not be used routinely for predicting risk of postoperative pulmonary complications but may be appropriate for patients with chronic obstructive pulmonary disease or asthma.
6. Spirometry is of value before lung resection in determining candidacy for coronary artery bypass; however, it does not provide a spirometric threshold for extrathoracic surgery below which the risks of surgery are unacceptable.
7. Pulmonary artery catheterization, administration of total parenteral nutrition (as opposed to no supplementation), or total enteral nutrition has no consistent benefit in reducing postoperative pulmonary complications.

PERIOPERATIVE MANAGEMENT AND PROPHYLAXIS

DIABETES MELLITUS (SEE ALSO CHAPS. 403–405)

Many patients with diabetes mellitus have significant symptomatic or asymptomatic CAD and may have silent myocardial ischemia due to autonomic dysfunction. Intensive (versus lenient) glycemic control in the perioperative period is generally not associated with improved outcomes and may increase the risk of hypoglycemia. Practice guidelines advocate a target glucose range of 100–180 mg/dL in the perioperative period. Oral hypoglycemic agonists should not be given on the morning of surgery. Perioperative hyperglycemia should be treated with IV infusion of short-acting insulin or subcutaneous sliding-scale insulin. Patients whose diabetes is diet controlled may proceed to surgery with close postoperative monitoring.

INFECTIVE ENDOCARDITIS (SEE ALSO CHAP. 128)

Prophylactic antibiotics should be administered to the following patients before dental procedures that involve manipulation of gingival tissue, manipulation of the periapical region of teeth, or perforation of the oral mucosa: those with prosthetic cardiac valves (including transcatheter prosthetic valves); prosthetic material used in valve repair (annuloplasty ring or artificial chord); previous infective endocarditis; cardiac transplant recipients with valvular regurgitation from a structurally abnormal valve; and unrepaired cyanotic congenital heart disease or repaired congenital heart disease, with residual shunts or valvular regurgitation at the site adjacent to the site of a prosthetic patch or prosthetic device.

AORTIC STENOSIS

Previous 2007 ACC/AHA guidelines have cautioned against surgery in patients with severe aortic stenosis, citing a 10% mortality risk. More recent guidelines, rooted in contemporary data, offer greater latitude for noncardiac surgery in appropriately selected patients with severe aortic stenosis. Among those who are asymptomatic with severe aortic stenosis, the ACC/AHA assigns a Class IIa, Level of Evidence C recommendation for moderate-risk surgery. In an analysis of patients undergoing moderate or high-risk surgery at the Mayo Clinic from 2000 to 2010, there was no significant difference in 30-day mortality between those with severe aortic stenosis and matched controls (5.9% vs 3.1%, p=0.13); however, those with severe aortic stenosis had more major adverse cardiac events (18.8% vs 10.5%, p=0.01), mainly due to heart failure. In sum, severe aortic stenosis is associated with adverse outcomes in patients undergoing noncardiac surgery; however, in contemporary cohorts this risk is less than has previously been stated. Balloon valvotomy is usually not recommended but may serve a role in the minority of patients who need "bridging" to a necessary surgery or procedure.

VENOUS THROMBOEMBOLISM

(See also Chap. 279)

Perioperative prophylaxis of venous thromboembolism should follow established guidelines of the American College of Chest Physicians. Aspirin is not supported as a single agent for thromboprophylaxis. Low-dose unfractionated heparin (≤5000 units SC bid), low-molecular-weight heparin (e.g., enoxaparin, 30 mg bid or 40 mg qd), or a pentasaccharide (fondaparinux, 2.5 mg qd) is appropriate for patients at moderate risk; unfractionated heparin (5000 units SC tid) is appropriate for patients at high risk. The use of direct oral anticoagulants may be an alternative to the use of prophylactic doses of low-dose unfractionated heparin and low-molecular-weight heparin; among patients immobilized after nonmajor orthopedic surgery, rivaroxaban 10 mg once daily when compared to enoxaparin was associated with a decrease in venous thromboembolic events, without a significant change in bleeding. Graduated compression stockings and pneumatic compression devices are useful supplements to anticoagulant therapy or as alternatives to anticoagulant therapy in patients at excessive bleeding risk.

481 Behavioral Economics and Health

Kevin G. Volpp, George Loewenstein, David A. Asch

Tobacco use, physical inactivity, unhealthy diet, excessive alcohol use, and other individual behaviors are estimated to underlie 40% of premature mortality in the United States. Approximately 75% of the $3.5 trillion currently spent on health care in the United States is attributable to cancer, heart disease, type 2 diabetes, and obesity, and each of these conditions is strongly influenced by behavior. Nearly one-half of patients prescribed medications to lower their cholesterol within 1 year following myocardial infarction stop taking these drugs—even when they are provided free of charge. Despite great advances in the science and technology of health care, a large gap separates theoretically achievable goals in health and health care from what individuals and populations actually achieve. Human behavior is both a major contributor to health problems and a barrier to the successful implementation of solutions to address them.

Recognizing that there are many reasons people do not take action to improve their health, behavior change experts have focused efforts on strategies targeted at individual behavior, introducing incentives for weight loss, medication adherence, and smoking cessation, environmental strategies such as mandated food labeling, and combination approaches. For example, Section 2705 of the Affordable Care Act (ACA) allows employers to provide incentives of up to 50% of total premiums based on outcomes such as reduced body mass index, lowered blood pressure or cholesterol, and smoking cessation; this legislation puts as much as $300 billion worth of employee health incentives in play annually.

Many of these approaches have built-in limitations, largely because they have been designed around the pervasive view that people reliably act to improve their self-interest. Existing policy solutions presuppose that health care decisions are rationally based economic transactions and that rational people will dispassionately assess the net present value of the costs and benefits of alternative courses of behavior and pursue the best path forward. These approaches are normatively appealing but seem better suited to support the health of people who behave as economists assume they do, and perhaps less effective when exposed to such realities of human behavior as limited attention, overconfidence, and problems of self-control. It is not just the magnitude of incentives that matters, but also other critical features such as the specific nature of rewards, feedback frequency, saliency, and framing. Public health programs, including those involving financial incentives, are more likely to achieve their goals if designed based not on how perfectly rational people *ought* to make health decisions but rather on how humans *actually* make them. The field of behavioral economics uses insights from psychology to identify ways that human decision-making often falls short of the ideal. The field aims to offer a more realistic account of human behavior, providing a natural framework for efforts to encourage changes in behavior.

CONCEPTS OF CLASSICAL ECONOMICS AND HOW THEY DIFFER FROM BEHAVIORAL ECONOMICS

Classical economics posits that individuals are rational utility maximizers, meaning that they are able to dispassionately identify alternative decisions, calculate the probabilities of and utility/disutility for each potential outcome, and then, through a process of backward induction, implement the decision that has the highest net present value. When it comes to health behaviors, classical economic theory would assume that if people are obese they must have decided that the costs of obesity are outweighed by the benefits of the behaviors that lead to it and that if people smoke they must have decided that the pleasures of doing so outweigh the costs. This assumption of rational utility maximization has two major consequences for public policy, both of which are applicable in the health domain.

The first is that conventional economic thinking radically limits the range of situations in which it makes sense to intervene at a policy level. Under the assumptions of conventional economics, regulatory interventions such as targeted taxes and subsidies are considered appropriate only in situations characterized by externalities (costs that an individual's actions impose on others such as second-hand cigarette smoke), the presence of "market failures" (e.g., monopolies), or the presence of certain types of information asymmetries. The second is that standard economics offers a relatively restricted array of policy tools, including taxes, subsidies, and mandates regarding patient education and information provision, and makes unrealistic assumptions about how each of these approaches will influence the behavior of individuals.

Behavioral economics builds on conventional economics by enriching its conception of individual behavior, offering enhancements on each of these dimensions. First, it broadens the range of situations in which policy interventions make sense by introducing the notion of "internalities." While externalities are costs (or benefits) individual behaviors impose on others, internalities are the costs individuals impose on themselves—typically their future selves. While interventions to address smoking and obesity can be justified on externality grounds (e.g., the health care costs are borne by individuals other than the immediately affected individual), they can also be justified on grounds of internalities—e.g., people often irrationally discount the delayed consequences of their behavior. In that sense, people might want to be protected not just from others, but from the decisions of their prior selves. Policy intervention can be further justified by the ubiquitous exploitation of individual weaknesses by businesses. Commercial enterprises may take advantage of such vulnerabilities for individual profit rather than customer health, such as with the formulation of tempting but unhealthy processed foods, the selling or prescribing of addictive substances such as cigarettes or opioids, or the pricing of meal "deals" that do not account for the health consequences of economically predatory offers. This behavior is found across industries: Credit card companies and automobile manufacturers lure new customers with "$0 down" and fleeting but appealing teaser rates of "0% interest," playing on the common propensity to focus on the present rather than on the future, as well as on people's overoptimism when it comes to their own future finances. Banks earn revenue by charging high fees for minor mistakes such as account overdrafts or breaches of minimum balance rules, often hiding the description of such fees in small print and complicated jargon. States market lottery tickets that return $0.45 on the dollar and promote these games in ways that ignore more realistic expectations using one-sided messages such as "you can't win if you don't play" rather than, for example, the equally accurate message, "you can't lose if you don't play."

Second, behavioral economics substantially broadens the range of potential policy interventions beyond those offered by traditional economics. Behavioral economics has become best known for the concepts of "libertarian paternalism" and "asymmetric paternalism." In contrast to "heavy-handed" paternalism, asymmetric paternalism attempts to protect people without limiting freedom of choice. That is, it is asymmetric because it seeks to help individuals who are prone to making irrational decisions without restricting the freedom of choice of those making informed, deliberate decisions. For example, arranging the presentation of food in a cafeteria line so that the healthy foods appear first is likely to increase the amount of healthy food chosen, without depriving those who want the unhealthy foods of the opportunity to purchase them. People who believe that individuals behave

optimally should not object to asymmetric paternalism because it does not limit freedom, but those who acknowledge the limits of human rationality should endorse such measures, assuming that they are designed with individuals' interests at heart. Frequently, these measures are called "nudges."

A nudge has been defined as "any aspect of the choice architecture that alters people's behavior in a predictable way without forbidding any options or significantly changing their economic incentives. To count as a mere nudge, the intervention must be easy and cheap to avoid." The most prominent, and to date successful, application of nudges has been the use of defaults to increase enrollment in defined contribution retirement savings plans and, secondarily, the use of automatic escalation to encourage higher savings rates. These ideas and research findings have had a major impact on retirement savings policies worldwide, including the Pension Protection Act of 2006 in the United States. Building on this success story in savings, and bolstered by the establishment of so-called "nudge units" worldwide, the nudge agenda has positioned behavioral economics at the center of public policy.

The applicability of behavioral economics to policy, including health-related policies, however, goes well beyond nudges. Many health-relevant insights from behavioral economics do not fit the definition of a nudge. For example, there have been incentive programs aimed at changing health behaviors for maximum cost-effectiveness, improvements in the delivery of health-related information, such as nutrition labels, and new designs for physician incentives or health insurance. A common theme of this work is its harnessing of predictable decision errors that usually harm people to, instead, help them to achieve longer-term health goals or other socially valuable purposes, much the way some martial arts redirect an adversary's strength against him.

Many of the same messages, incentives, and choice structures used so effectively to lure people into self-destructive health behaviors can be redirected to attract them to healthier choices that improve their long-term health and well-being. In addition, some features of human decision-making that are not recognized by traditional economics but are not really examples of decision errors, such as our propensity to experience regret when we make a bad choice and our aversion to putting ourselves into such situations (a phenomenon known as "regret aversion") can also be exploited in the service of improving health behaviors and outcomes.

There is a common misconception that if you deploy financial incentives in order to promote behavior change, then you are engaged in behavioral economics. But that kind of activity is not behavioral economics; it is simply economics. Indeed, a large number of everyday transactions, such as being paid to go to work or getting a fine for parking in the wrong place, reflect traditional economic incentives to encourage or discourage certain behaviors. However, introducing incentives in situations, such as those characterized by internalities, in which traditional economics would suggest the incentives are unnecessary *can* be viewed as applications of behavioral economics.

Perhaps more importantly, a central lesson from the field of behavioral economics is that how incentives are delivered can matter more than their objective magnitude. There are ways of delivering large incentives that make them ineffective in changing behavior, and there are ways that can greatly magnify the effectiveness of comparatively small incentives. This observation is a source of optimism because it suggests that, with careful design, we can leverage relatively small investments to improve public health.

USING BEHAVIORAL ECONOMICS TO PROMOTE SELF-BENEFICIAL HEALTH BEHAVIORS

Behavioral economics builds on neoclassical economics, which has at its core *expected utility theory*. Expected utility theory both presumes to describe how people make decisions and offers a prescription for how such decisions should be made. While utility maximization is a powerful normative model of how we ought to behave, it turns out to be a poor descriptive model of how real people actually behave. Efforts to alter human behavior that rely on this inaccurate and incomplete model often fall short.

TABLE 481-1 Traditional vs Behavioral Economics

TRADITIONAL ECONOMICS	BEHAVIORAL ECONOMICS
Core theory: Expected utility maximization	Core theory: Prospect theory
Assumes perfect rationality	Recognizes that people make decision errors
Starting point independent	Assessment depends on your starting point
Framing doesn't matter	Framing affects assessment even when utilities are the same
Stable preferences	Time-inconsistent preferences
People discount the future at constant rates	People discount the near future to a greater degree and have time-inconsistent discounting
Intervene only when my actions adversely affect others (negative externalities)	Consider interventions when people will harm their future selves (internalities)
Regulations and policies generally geared to protecting people from the actions of others	Regulations and policies often geared to protecting people from themselves

Over the past several decades, behavioral economics has described various ways in which people's decisions differ from standard economic models **(Table 481-1)**. While economists mapped out concepts of "bounded rationality" in the 1950s and identified limitations in the dominant expected utility model of decision making under risk, the publication of the article "Prospect Theory" by Kahneman and Tversky in 1979 is widely credited with being seminal in the development of behavioral economics. Prospect theory provides an overarching conceptual framework for describing observations about human behaviors that could not be explained by expected utility theory.

Although these deviations from expected utility theory can be seen as psychological foibles and errors, the real value of this work has come less from identifying these errors and more from recognizing that they occur in predictable ways. It is the predictability of these errors that allows the design of strategies to overcome them **(Table 481-2)**. Indeed, it is the predictability and reliability of a number of key features of human decision-making identified by behavioral economics, including but not limited to those connected to prospect theory, that allows them to be used in order to promote self-advantageous health-related behaviors.

Loss Aversion and Framing Effects Key tenets of prospect theory include: (1) how people feel about a set of possible outcomes depends on their starting point; this is the notion of reference-dependence in which decision-makers evaluate outcomes as gains or losses depending on their starting point; (2) people dislike losses much more than they like equivalent-sized gains, a phenomenon known as

TABLE 481-2 Key Decision Errors and Suggestions for Addressing Them

Present-biased preferences	Provide feedback and rewards quickly
Nonlinear probability weighting	Motivate people with probabilistic rewards (lotteries)
Overoptimism and loss aversion	Get people to precommit and put money at risk as an effective motivational tool
Peanuts effect	Deliver rewards in bundles, avoiding many small rewards
Narrow bracketing	Frame rewards in terms of effort per day rather than per month or year
Regret aversion	Help people anticipate the regret of poor choices
Defaults/status quo bias	Change the architecture or environment of choice to shift the path of least resistance to favor healthy decisions
Rational world bias	Move beyond the assumption that simply providing information will lead to desired behaviors

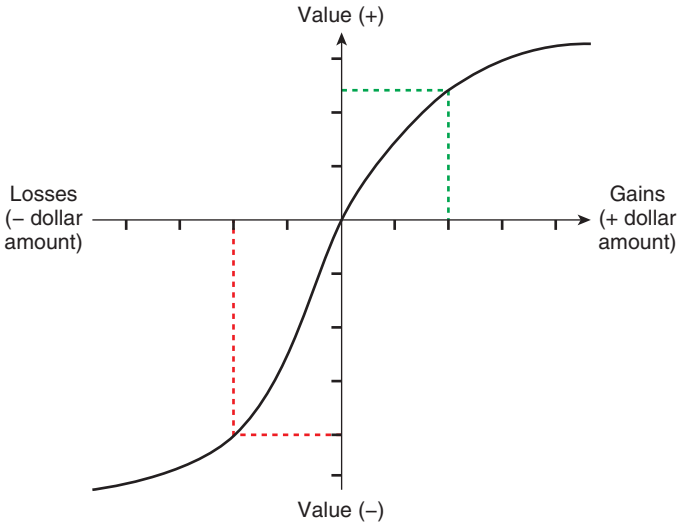

FIGURE 481-1 Prospect theory. *(Adapted from D Kahneman: Thinking, Fast and Slow. New York, NY: Farrar, Straus and Giroux, 2011.)*

"loss aversion"; and (3) there is diminished sensitivity to both gains and losses **(Fig. 481-1)**.

One example of how we can apply the insights of loss aversion can be seen in designing provider payment systems. Financial incentives to physicians to achieve quality goals might be presented—"framed" in the language of behavioral economics—as either rewards (in which physicians receive a bonus if, for example, they increase their colorectal cancer screening rates or increase the percentage of their patients who reach a glycosylated hemoglobin target) or penalties (in which physicians would fail to receive an expected payment if they do not meet these targets). Classical economists would consider equivalently sized rewards and penalties as identically motivating because each reflects a structure in which one receives $X for a certain outcome (Fig. 481-1). However, loss aversion reminds us that the disutility of losing money is much greater than the utility of gaining the same amount of money. A number of studies have shown that people have a "loss aversion ratio" in a range of 1.5 to 2.5. That means that a potential penalty of $1000 for failing to meet a quality target ought to be about as potent a motivator as a potential reward of $1500 to $2500 for meeting the same target. That multiplier is nonsensical from the standpoint of classical economics, but as an empirically verifiable descriptor of human behavior, it can be exploited in the designs of programs for clinicians or patients to improve health.

All of us—including physicians—are highly susceptible to how information is framed. In a set of experiments, patients, students, and physicians were presented cases of lung cancer that could be treated either by surgery or radiation therapy. Among all three groups, the choice of surgery was more popular when its outcomes were framed in terms of the probability of survival (e.g., a 68% chance of living for >1 year) rather than in terms of the probability of death (e.g., a 32% chance of dying by the end of 1 year). We can say that such sensitivity to framing is irrational since a 68% chance of survival is logically equivalent to a 32% chance of dying—but these irrational decisions fall into predictable patterns of behavior, and that predictability can be used to influence those decisions. This means that clinicians have enormous opportunities to lead patients toward particular decisions by framing the outcomes of those decisions in specific ways, even as they remain truthful. Such an understanding could lead to the view that clinicians should be careful to balance their framing (for example, by following up the statement of 68% chance of survival with a statement like "That means there is a 32% chance of death") in order to provide information in a way that is likely to lead to a particular choice. Alternatively, it could lead to the view that clinicians should deliberately frame outcomes in certain ways in order to lead patients to particular choices—a much more paternalistic stance. Patients often rely on trusted clinicians to help them make the best decisions, and in some settings, that reliance may justify using the principles of behavioral economics strategically even if the same actions in other settings might be seen as paternalistic, anti-libertarian, or coercive.

Loss Aversion and Overoptimism The power of loss aversion can be most effectively leveraged when combined with a well-documented decision error: overoptimism, or unrealistically high expectations about future outcomes. Overoptimism is especially pronounced in the context of people's predictions about their own likelihood of exerting self-control, sometimes referred to as the "false hope syndrome." The optimism that "*This* time, my efforts at weight loss will succeed!" or "*This* year, I will follow my New Year's resolutions!" often reveals itself to be false. Although in some contexts overoptimism seems to be beneficial, it can also result in suboptimal patterns of behavior. For example, people prefer paying a flat rate for gym memberships even though they would spend less if they were to pay on a per-visit basis, in part because they overestimate their future gym attendance. Indeed, many people enter into commercial weight loss programs and pay for a full year up front because they are overly optimistic about their chances of success.

Loss aversion can produce a variety of undesired behaviors, from excessive risk aversion to the tendency for people to hold on to losing investments, such as houses or stocks, for too long. However, loss aversion can advance individual or social goals. Framing reward outcomes in terms of losses by "fronting" a sum of money that gets lost if goals are not met, is often more motivating than providing equivalent gains for meeting goals (the economic but not psychological equivalent). Yet, despite the greater behavioral potency of losses, program administrators are often reluctant to use loss framing, perhaps because such programs can seem more punitive than organizations may wish to appear. However, it is possible to take advantage of loss aversion by designing programs in which people voluntarily put their own money at risk in the service of achieving health-behavior goals that they themselves desire.

The combination of overoptimism and loss aversion has been used to help people lose weight by giving them the opportunity to participate in deposit contracts, in which they could deposit $0.01–$3.00 per day of their own money, with a 100% match. Participants reported their weight daily and received the sum of the deposit and the matching funds each day they were on track to meeting their monthly weight loss targets, but they forfeited both if they were not on track. The deposit contract leveraged participants' overly optimistic self-predictions of how much weight they would lose as well as loss aversion once deposits were made. Once deposited, however, such optimism can become a self-fulfilling prophecy as loss aversion provides extra motivation to meet goals. In this 16-week study, average weight loss was 14.0 pounds in the deposit group compared with 3.9 pounds in the control group. This work was extended in a 32-week study in which weight loss was sustained for the duration of the intervention (8.7 vs 2.2 pounds in the control group).

Although these results are promising, to be effective as a health strategy, this approach needs to achieve high ongoing participation rates to sustain its population effect. Deposit contract approaches are powerful motivators of behavior change, but they are not always popular, even among those who initially opt to try them, posing a challenge to long-term success.

Peanuts Effects The prospect theory value function assumes diminishing marginal utility, which means that small gains and losses are disproportionately motivating relative to larger ones (e.g., two $500 rewards would be more potent than one $1000 reward). However, this may be too simple for small rewards (e.g., two $5 rewards may be less motivating than one $10 reward). This "peanuts effect" may be part of the reason why charities and retailers often describe costs in terms of "pennies a day." This observation challenges the expected efficacy of programs that emphasize efforts to repeatedly achieve small changes such as in weight loss programs. It is easy for a patient to rationalize that no single cigarette causes lung cancer, that no single snack leads to obesity, or that no single trip to the gym prevents heart disease.

If self-destructive patterns of behavior, such as cigarette smoking, weight gain, or cell phone use while driving, are seen as individual instances rather than parts of a composite whole, it is easier to understand how they can be seen as acceptable. The pleasure of smoking a cigarette or eating a dessert and the convenience and engagement of conducting business or socializing in otherwise "dead" travel time are immediate and tangible, but the marginal costs—increased risks of developing lung cancer, being overweight, or having a car accident—seem inappreciably small. Across a lifetime or a population, however, the cumulative costs and/or probabilities are not small at all.

The tendency to underweight small outcomes can also be used to people's advantage, such as by inducing people to put away small sums for retirement savings in short cycle lengths or to make small periodic investments in their health via medication adherence. In each of these efforts, we need to think asymmetrically. In our incentive programs we should provide frequent (often daily) feedback on rewards because of present-biased preferences, but if we are *delivering* financial rewards, we want to aggregate them so that the rewards appear substantial enough to warrant attention. To use the peanuts effect to advantage, one might alert people to their rewards daily but then deliver them monthly to create larger aggregate payments.

PRESENT-BIASED PREFERENCES

Another central observation from behavioral economics is the concept of hyperbolic discounting, or "present bias." It is standard in conventional economics to assume that people discount the future; for example, $1000 today is worth more than $1000 a year from now, since money can be invested and earn interest. However, people tend to discount outcomes that are close in time more steeply than outcomes that are farther off in time; the degree of time discounting is disproportionately greater for short time delays than for long ones, in contrast to the assumption of standard economic models.

The medical implications of present bias are profound. For example, most people would desperately like to avoid a stroke, and many patients with hypertension have an understanding that taking their antihypertensive medications is one of the best ways to avoid a stroke in the future. While the classical economist would see daily adherence to antihypertensive treatment as a trivial cost to avoid the major cost of a future stroke, the stroke that is avoided is far in the future and uncertain; moreover, the stroke that is prevented is never noticed. In contrast, even the relatively small effort required to stay on antihypertensive medication is incurred in the present and comes without any immediate compensatory benefit. To the extent that patients overly discount the future harms of a later stroke, they will be less motivated to invest today in their own medication adherence. To the classical economist, these patients are behaving irrationally because they are failing to make small investments that, if they did the calculations, would clearly make them more likely to be substantially better off; this reasoning is parallel to how classical economists consider people who undersave for retirement (the vast majority of Americans) to be irrational. To the behavioral economist, these errors are targets for therapy, in the way that we can see genetic mutations or defects in chemical pathways as therapeutic targets in the management of illness.

Present bias is somewhat subtler than simply steep discounting of the future. In fact, it reflects *two* behavioral tendencies: (1) the tendency to overweight immediate costs and benefits relative to those occurring in the future, as just discussed, and (2) the tendency to take a more evenhanded approach to *future* costs and benefits. People are much more willing to begin dieting *tomorrow*, because the overweighting of immediate costs deters us from the immediate deprivation of dieting, and the more balanced perspective on delayed deprivation makes us willing to impose these costs on ourselves in the future.

Although present-biased preferences typically promote unhealthy behaviors, policymakers can use them for beneficial effects. The motivational impact of benefits and costs, such as rewards for good behavior and punishments for bad behavior, can be increased substantially if they are made immediate. These consequences should coincide as closely as possible with the timing of the behaviors they are meant to encourage or deter. Funds for this could be provided by employers or insurers, for whom this might be a cost-effective way to improve worker health and productivity.

Such programs have been shown to have dramatic effects in the area of drug addiction. This success is particularly striking, because many individuals with drug addiction already face major adverse consequences, such as loss of livelihood and disenfranchisement from their families; yet these costs are often insufficient to motivate abstinence. Similarly, small incentives offered on proof of abstinence have succeeded in tripling smoking-cessation rates where the far larger (but delayed) incentives in terms of improved health have failed. Small, daily, lottery-based incentives have significantly increased medication adherence and weight loss in part because they bring immediate rewards (money, excitement) to a situation in which the benefits of avoiding ill health are typically distant and uncertain.

Thus, rather than requiring individuals to make decisions based on consideration of their long-term best interests, it might be useful to change short-term incentives so that beneficial actions are easier and more attractive to choose or small costs—"hassle factors"—are put in the way of behaviors adverse to health. Some school districts have begun to use this approach by removing various products such as soda and candy from vending machines so that the cost of obtaining them now includes a walk off campus, while healthier food and beverage options are immediately and readily available. In addition, people's willingness to commit to future changes can be leveraged by giving them choices between health-benefiting and health-harming behaviors well before they actually have to act on them. An example of this is scheduling gym visits and laboratory tests to monitor cholesterol ahead of time or having employees preorder lunch shortly after breakfast when they are more likely to select healthy meals both due to present bias and to their current lack of acute hunger.

Nonlinear Probability Weighting Prospect theory also encompasses a second important dimension: the way that people weight probabilities. In contrast to the standard expected utility model, which assumes that people weight outcomes according to their raw probabilities, prospect theory assumes that people overweight, but are insensitive to differences in, small probabilities—for example, between a 0.001 and a 0.00001 chance of winning a prize, even though the probabilities differ by several orders of magnitude—except where they provide a transition to certainty. Such overweighting of small probabilities is partly responsible for the enormous attraction of lottery tickets, which are widely seen by experts as a poor use of money; yet, like present-biased preferences, this overweighting can be used to advantage in public health interventions.

Following these cognitive pathways, lottery-based reward systems have been introduced in programs aimed at motivating diverse health behaviors (described more fully below). These interventions exploit overweighting of small probabilities and also play on other psychological insights. Because people tend to be motivated by both the experience of past rewards and the prospect of future rewards, these lottery-based systems provide frequent small payoffs and infrequent large payoffs. This approach has been demonstrated to be effective in a variety of areas, including helping people lose weight (52.6% of people achieve 16-week weight loss goals compared with ~10.5% in a control group) and reducing medication nonadherence (from ~23% to ~3%). However, results across studies and contexts have been inconsistent, suggesting that the active ingredients of these lottery-based incentives have not been fully elucidated.

Regret Aversion People dislike regretting decisions they have made, often voicing laments such as "If only I had . . . ." Contemporary rhetoric recasts one form of regret aversion as "FOMO," the fear of missing out. Moreover, people are sufficiently far-sighted to anticipate possible future regret and seek to make decisions today that reduce that risk in the future. The avoidance of anticipated regret is a useful exception to present-biased preferences.

Regret aversion helps to explain the success of the Dutch postal code lottery, in which winning postal codes are selected and those living within the selected areas who purchased tickets receive prizes. Those

who did not purchase tickets learn that they would have won had they done so. Individuals see their neighbors winning large prizes that they do not share, or fear that this will occur, and their desire to avoid future regret drives subsequent lottery participation.

Anticipated regret has been shown to affect a variety of preventive behaviors, such as the significant increase in vaccination use among people who experienced illness after failing to get vaccinated. Lottery-based incentive programs where eligibility is conditioned on adherence (for example, you aren't eligible to play the lottery unless you had taken your medication or checked your blood pressure the previous day) can incorporate regret aversion into their design by notifying both winners and losers. Those whose number comes up but are ineligible for a reward because of nonadherence are told they would have won had they only taken their medication, checked their blood pressure, or done whatever it was the lottery program was designed to promote. Because people hate the feeling of regret, they are more likely to engage in behaviors to avoid that feeling. Indeed, the advertising campaigns of some traditional lottery systems take advantage of regret aversion. Many people play the same favorite number when the buy lottery tickets. It easy to imagine the disappointment you would feel if you missed buying a ticket one week and that was the week your favorite number came through. Advertising slogans like "don't let your number win without you" keep people in the game in order to escape that feeling of regret. The same techniques used to promote the marketing of lottery tickets can be deployed toward health promotion.

Defaults Although many interventions playing on behavioral economics do not qualify as "nudges," nudges remain a powerful way to influence choice. Traditional economic thinking ignores the power of the default option—the path that is "selected" when no selection is made. However, the default bias, or status quo bias, reflects our tendency to take "the path of least resistance"—to continue doing what we have been doing, or to do what comes automatically, even when superior alternatives exist. Defaults have been blamed for a wide range of suboptimal outcomes, from the failure of employees to put aside retirement funds in companies whose default contribution rate is zero, to suboptimal allocation between investment alternatives, to excessive consumption of French fries and large sodas as part of "supersized" meals at fast-food franchises. Likewise, countries and states that have "opt-in" policies for organ donation—that is, the default is nonparticipation—tend to have lower donation rates than those with opt-out defaults or (as is increasingly viewed as the best compromise) those in which citizens are required to make an active choice about whether they want to be listed as a donor. Defaults that prioritize comfort over so-called "heroic measures" have been shown to increase the rate at which patients with terminal lung diseases choose comfort-oriented plans of care, and they could be used more widely to encourage the choice of beneficial health options that would vary based on the clinical context.

If used tactically, a choice architect (the person who makes decisions on how choices are presented to the end user) can utilize defaults such as changing scheduled automatic prescription refills from 30 to 90 days (or longer) for patients requiring lifelong chronic-disease therapy or changing the default option in fast-food restaurants in combination meals from large sodas to small sodas or water or from French fries to carrots unless you ask for French fries to help propel people toward self-beneficial behaviors. A default toward prescription of generic medications embedded in a health system electronic order entry system moved generic prescribing to nearly 100% in a context in which previous attempts at physician education had shown no effect at all. Changing the default framing of an invitation to patients with poorly controlled diabetes to join a free remote glycemic monitoring program tripled enrollment from ~13% to 37%.

Such approaches cost nothing, since a default has to be set one way or another, preserve freedom of choice, and could change behavior substantially. We miss out on many opportunities to nudge people toward healthier lifestyles when we do not consider the default option as a tactical choice to be actively incorporated into an overall health-promoting strategy.

The Rational-World Bias Perhaps the most consequential decision error affecting health-related behaviors is the tendency of public health officials and private-sector benefit designers to make policy decisions based on the assumption that people's choices are deliberative and rational. This in turn leads to assumptions that information provision is all that is needed for optimal decision-making and that, when financial incentives are offered, the amount is all that really matters.

One significant manifestation of the rational-world bias is the complexity of health insurance plans. Health insurance is complicated for many reasons, but one reason is that health care itself is complicated and health insurance plans are full of deductibles and copayments and other financial incentives that are designed by economists and actuaries to encourage insured patients to direct their care in specific cost-minimizing and health-maximizing ways. For these built-in incentives to exert their desired influence, however, patients need to understand the incentives they are facing, and there is considerable evidence that they do not. This complexity of insurance benefit design, rather than creating perfectly tailored incentives, is part of insurance design's undoing—because an incentive that cannot be understood cannot be effective. Most consumers lack an understanding of the most basic insurance concepts, such as deductibles, copays, and coinsurance, and, when given a simplified version of a traditional insurance plan, are unable to compute the costs they would incur for basic services.

Giving a nod to the benefits of simplicity, the ACA in the United States requires insurance plans to be presented in a standardized document that describes plan features such as premiums, deductibles, and coinsurance. However, describing something that is inherently complex in simple terms raises the risk of glossing over important subtleties. A more productive approach would be to provide consumers with a truly simplified insurance product. For example, insurers might create a plan designed with copayments only, since copayments are most easily understood by consumers: copayments are analogous to paying a price for a good or service when shopping, whereas coinsurance and deductibles make it difficult for people to estimate how much their care would cost. It is difficult, if not impossible, for a consumer to estimate 10% coinsurance on a hospital stay or an emergency room visit since they have no idea of the full amount on which the 10% will be calculated. For medical markets and patient cost-sharing elements embedded in plan design to affect decision-making *ex ante*, consumers need some way of accurately gauging not only benefits and risks of treatments but also the costs. This should occur before receiving a diagnostic test or treatment as opposed to what typically happens now: a medical bill is received after the fact.

Another manifestation of the rational-world bias is the more insidious and pervasive belief that if only people knew more about how to advance their health they would do so. This error leads to making education the centerpiece of many health interventions even though public health experts have long recognized that knowledge alone rarely translates to health-enhancing behavior. For example, nearly everyone knows the health hazards of smoking. While raising and maintaining awareness of the dangers of smoking is an important goal, the financial budgets of the Centers for Disease Control and Prevention, or the time budgets of clinicians, might be more efficiently allocated toward efforts to change behavior that do not presume that the deficit is a lack of knowledge. Indeed, it has been argued that smokers tend to *overestimate* the hazards of tobacco, just as many women tend to *overestimate* their risks of developing breast cancer. In these cases, better or more accurate education might lead people to *lower* their estimates of risk and might, if they were perfectly rational, lead them to reduce health-promoting behaviors. In cases where the deficit is not in knowledge but in behavior, reliance on education as a primary avenue for reducing health risks may divert efforts and resources from other activities that might be much more effective.

APPLICATIONS

Weight Loss Efforts to combat obesity using incentives started in the 1970s. This early work was motivated by the observation that participants who deposited money and other valuables with a therapist

and signed contracts in which return of their valuables was contingent on progress toward prespecified goals lost tremendous amounts of weight. Even though participants received no training in weight loss or maintenance strategies, participants lost an average of 32 pounds. This small initial study lacked control groups and long-term follow-up but provided an important proof of concept.

In the first systematic study of deposit or precommitment contracts, participants responding to an advertisement for a weight loss program were informed that study participation required a deposit of $200 (1974 dollars), which would be fully refunded contingent on satisfactory weight loss. After an 11-session, 10-week program, those who received incentives for losing weight or for limiting calories lost significantly more weight than those who received incentives for attending sessions. Of the participants in the former two groups, 70% lost >15 pounds. The major limitation to this approach was that only 15% of the prospective participants who responded to the initial newspaper advertisement ended up enrolling, suggesting that deposit contracts that require participants to commit substantial funds up front are very effective for people who agree to participate, but that this requirement likely deters a substantial portion of high-risk participants from entering and its effectiveness may just as much reflect selection of those highly motivated to lose weight.

A subsequent study tested the effects on weight loss of deposit contracts of $30, $150, or $300, with the deposits returned based on either individual or group weight loss over 15 weeks. Participants in the intervention group could win $1, $5, or $10 per pound lost up to a maximum cumulative weight loss of 2 pounds per week (either individual or group average). Mean weight loss was large in all three groups but did not differ significantly based on contract size. However, the proportion who reached the goal of a 30-pound weight loss was significantly higher in the larger dollar groups.

Because it is increasingly difficult to shed pounds as weight is lost, the investigators also tested whether a deposit contract with increasing payments ($5, $10, $20, $40, or $75) for each 5-pound increment of weight loss would be more effective than offering $30 for each 5-pound increment of weight loss. Participants in both conditions were also offered a maintenance program requiring a $100 deposit, returned in $25 increments for attendance at follow-up visits every 3 months. The increasing contract resulted in qualitatively larger weight loss during the weight loss phase, but the maintenance program did not prevent weight regain, likely because the magnitude of the deposit contract for maintenance was small and feedback was infrequent (only every 3 months).

Paying participants for weight loss using direct payments was less effective than deposit contracts. In a randomized trial, cash payments up to $25 per week for making 100% of proportional progress toward goal, $12.50 for 50% of goal, and $2.50 for not gaining weight did not result in greater weight loss in the payment group than among control subjects.

Studies that have shown no effects on either initial weight loss or maintenance typically have used incentives of small magnitude or were targeted at behaviors like attendance at weight loss programs that, by themselves, do not ensure weight loss. In recent years, weight loss incentives have become a common feature in programs used by employers and health plans, and a variety of start-ups like *stickk.com* and *dietbet.com* use deposit contracts as a way of trying to help people lose weight.

Newer approaches have provided proof of concept that daily lottery-type incentives and precommitment contract incentives promote initial weight loss over 16 weeks (lottery = 13.1 pounds; $p = .014$ for lottery vs control; deposit contract = 14.0 pounds; $p = .003$ vs control; **Fig. 481-2**). However, participants regained most of the weight they had lost over the following 3 months. Longer trials (8 months) found no difference in effectiveness of deposit contracts for continuous 8-month weight loss versus 6-month weight loss with 2 months of maintenance, but both were successful in achieving a mean weight loss of ~10 pounds. Subsequent tests included an employer-based study showing greater effectiveness of team competitive versus individual incentives, although there was a confound in that participants in the teams had the potential to win more money than those in the individual arms.

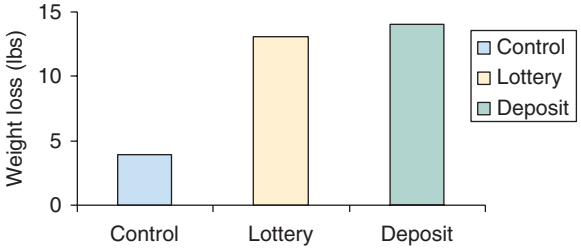

FIGURE 481-2 Weight loss in incentives versus control. *(Figure created using data from KG Volpp et al: Financial incentive-based approaches for weight loss: A randomized trial. JAMA 300:2631, 2008.)*

While both of these studies suggest that financial incentives promote weight loss, many employers use premium adjustments (increases or decreases to health insurance payments) as their standard approach to using financial incentives for health promotion. The effectiveness of premium-based financial incentives to promote weight loss has been assessed in a workplace wellness program and with a goal of losing 5% of initial weight over the next year. Participants were randomly assigned to a control group with no other intervention or one of three financial incentive groups. Two intervention groups were offered a premium reduction of $550 if they achieved their weight loss goal by 1 year. The "delayed" group would receive the premium adjustment in the following year, spread across each pay period. The "immediate" group would have their premiums adjusted as soon as the weight loss goal was met. A third intervention group was offered a daily lottery with about a 1 in 5 chance of winning $10 and a 1 in 100 chance of winning $100. To be eligible to win each day, participants had to weigh in and be on track to lose 5% of their initial weight by 6 months, with maintenance for the subsequent 6 months. After 1 year in the program, none of the intervention approaches showed a significant degree of weight loss. The control group gained <0.1 kg.

The relative ineffectiveness of premium-based financial incentives is not surprising given their design. Premium adjustments are logistically appealing because the infrastructure to do so is already in place, there isn't strong evidence for their effectiveness and theory argues against it. Such incentives are typically hidden in paychecks that are directly deposited in bank accounts and may go unnoticed by the individual. While a $550 incentive seems like a large amount, it is only $20 in each biweekly paycheck. Typically, these incentives are administered on an all-or-nothing basis contingent on meeting a specific threshold such as a body mass index of ≤25 kg/m^2, meaning that those who are close to that target may be motivated by a goal within reach, but those who are farther away (and have the most weight to lose and the most health to gain) may be less motivated (perhaps even demotivated) by a goal that does not seem attainable. The best evidence and theory now suggest that the standard approach of using premium-based incentives is not very effective and that employers should consider alternative delivery channels for financial incentives to promote health.

A common problem employers and health plans struggle with is getting high levels of engagement among employees/health plan members. Weight Watchers, the largest commercial weight loss program in the United States, worked with a team of academic investigators to conduct a randomized controlled trial involving >23,000 participants testing the impact of offering employer subsidization of Weight Watchers membership fees of 50%, 80%, 100%, or 50% that could turn into 100% conditional on attending at least three Weight Watchers classes a month. Higher subsidies led to higher program enrollment ($p < .0001$). Enrollment differed significantly by subsidy level ($p < .0001$). The 100% subsidy produced the highest enrollment (7.7%), significantly higher than each of the lower subsidies (vs 80% subsidy: 6.2%, $p = .002$; vs 50% subsidy: 3.9%, $p < .0001$; vs hybrid: 3.7%, $p < .0001$). Enrollment in the 80% subsidy group was significantly higher than both lower subsidy groups (vs 50% subsidy: 3.9%, $p < .0001$; vs hybrid: 3.7%, $p < .0001$). Among enrollees, however, there were no differences among the four groups in attendance or weight loss. In all groups, overall weight loss

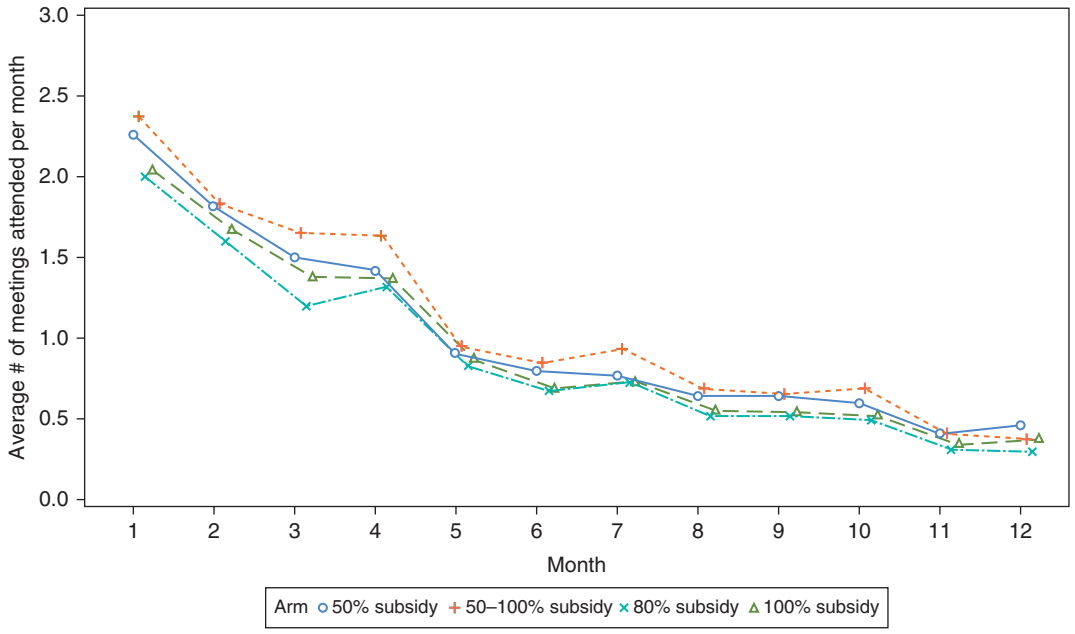

FIGURE 481-3 Attendance rates at Weight Watchers over time in different subsidy groups. *(Reproduced with permission from LK John et al: The effect of cost sharing on an employee weight loss program: A randomized trial. Am J Health Promot 32:170, 2018.)*

was modest, with a mean weight loss of 2.6 pounds (95% confidence interval [CI], 5.7-pound loss to 0.3-pound gain) in the 100% subsidy arm; 1.5 pounds (95% CI, 5.6-pound loss to 1.3-pound gain) in the 80% subsidy arm; 3.8 pounds (95% CI, 7.9-pound loss to 0.4-pound gain) in the 50% subsidy arm, and 4.0 pounds (95% CI, 8.1-pound loss to 0.1-pound gain) in the hybrid subsidy arm. In all arms, attendance rates dropped steadily over time, suggesting that while the hypothesized trade-off between higher subsidies and lower ongoing engagement in the program did not exist, ongoing participation is a challenge across the board, and subsidies that lower the cost of participating are insufficient to achieve high levels of ongoing engagement **(Fig. 481-3)**.

In another study, 281 overweight and obese adults were randomly assigned to a control group or one of three incentive groups for a 13-week physical activity program. All participants were given a goal of achieving 7000 steps a day, tracked automatically using their smart phones. Participants in each of the three incentive arms were offered the same magnitude incentive, $1.40 per day, and were told that accumulated earnings would be sent via a check at the end of each month. However, the incentive in each group was framed differently. In the standard gain incentive group, participants were told that they could earn $1.40 each day they achieved the goal. In the regret lottery incentive group, participants were in a daily regret lottery in which they had an 18 in 100 chance of winning $5 and a 1 in 100 chance of winning $50, which averages to $1.40 per day. In the loss framing incentive group, participants were told at the beginning of each month that $42 had been placed in a virtual account and that they would lose $1.40 each day the goal was not achieved. During the 13-week intervention, participants in the control, standard gain, and regret gain arms achieved their daily step goal ~30%, 35%, and 36% of the time, respectively, but the gain-framed incentive arms were not significantly different from the control arm. However, in the loss framing group, participants achieved the goal 45% of the time, a 50% relative increase, which was significantly greater than the control arm (p = .001). This study demonstrated how loss framing can be used to motivate behavior change. It is also one of the first studies to create a loss frame without requiring participants to put their own money at risk using a deposit contract. This is important because fewer people are willing to engage in deposit contract-based incentives than reward-based incentives.

Experience with behavioral economics and weight loss provides several general lessons that are transferable to other health applications. While early studies largely emphasized research in the size of financial incentives, later studies have revealed that the design of the incentive strategy is at least as important. Moreover, designs can vary considerably based on the timing of incentives that can be immediate or delayed, or frequent or one time; the setting of targets that can be achievable, aspirational, or demotivating; the certainty of incentives that can be fixed or probabilistic; the channel for incentives that can either be delivered separately or bundled through payrolls; or the framing of incentives as gains or losses. Classical economists would see only the size of the incentive as an available lever for motivation, but behavioral economists face a much larger set of considerations in designing and testing effective therapies.

Medication Adherence Numerous studies have shown that at least a third of patients fail to adhere to medication regimens. One approach to improving medication adherence is to change some of the underlying defaults by, for example, using 90-day prescriptions for chronic illness medications as opposed to 30-day prescriptions. While we are unaware of empirical evidence supporting longer prescription cycles, it seems logical that adherence rates would be higher over a year if people had to get refills three times as opposed to 11 times—the latter provides more opportunities to forget, experience delays, or fall off the wagon. Automatic refills through prescription mail order might similarly prevent some people from inadvertently falling off the wagon of medication adherence, giving them one less thing to think about or fail to think about.

Ninety-day prescriptions or automatic refills could be set up as the default, and patients or their providers could opt out if desired. Of course, opt-out defaults are not always possible. A large pharmacy benefits manager wanted to encourage automatic refills for patients on long-term medication but could not have members opt out of such a system because of the potential that those who missed the implications of the opt-out would be surprised or angry about finding credit card charges for automatic refills. Using active choice—i.e., requiring customers to make an explicit decision rather than only providing the service to those who proactively opt in—the company also presented options in a way that highlighted the convenience of automatic refills: "We can send your refills to you automatically or you can get your refills manually if you prefer." This resulted in more than twice as many patients choosing to be in the automatic-refill program as compared with opt-in.

A feature of many health insurance plans is that they require patients to pay some costs out of pocket and hence discourage the use of a number of high-value elements of care, such as the treatment of

hypertension or the use of statins by patients with diabetes—care that is widely seen as worth its cost. Support for the use of health insurance deductibles that require patients to have "skin in the game" for their health expenditures derives from insurance theory as well as the seminal RAND health insurance experiment, which demonstrated that these deductibles help overcome moral hazard and reduce the consumption of health care services. Copayments, deductibles, and other out-of-pocket costs make consumers more cost conscious and so aim to make them better shoppers for health care services. Indeed, the rise of high-deductible health plans largely aims to increase patients' skin in the game, to make them more value-conscious shoppers.

However, while deductibles and copayments make sense as a way to reduce overutilization of some lower-value health care services, deductibles and copayments make considerably less sense for medications and services that are high value and low cost—e.g., when patients receive medications to manage their hypertension, diabetes, or hyperlipidemia. Given that deductibles and copayments are designed to reduce utilization, why would we ever want to apply them to antihypertensives or statins or insulin given the high health value of these drugs? Why put any barriers between patients and these drugs? Indeed, as the RAND health insurance study showed, high-deductible health plans are as likely to discourage the use of high-value services as the use of low-value services. Because patients lack knowledge about what tests or services are of high or low value and do not have information about the relationship between price and quality, such plans discourage spending on *all* tests and services, including those of high value.

Value-based insurance design—which involves discounting, or making free, services that are deemed to be high in value—is an attempt to sharpen the blunt incentives inherent in deductibles and copayments. Value-based insurance design was inspired by research that showed the use of higher copayments significantly reduced the use of services such as prescriptions but ultimately raised costs because lower rates of medication nonadherence led to higher rates of emergency department visits and adverse outcomes. Extrapolating from these results, it was natural to conclude that lowering cost sharing for high-value activities, such as taking medications for chronic conditions, would increase adherence and potentially thereby reduce costs. The ACA incorporates a kind of value-based insurance design in its requirement that preventive services be offered to patients at no charge.

Unfortunately, value-based insurance design has not delivered on the hope that it would both save money and significantly improve health. From the perspective of the purchaser (for example, the employer or insurer), the economic impact of value-based insurance design depends on whether it can make enough people adherent who were previously nonadherent—and on the health and cost consequences of that improved adherence—to offset the loss of the copayments from those who were already adherent. Although some experimental tests of value-based insurance design have found that copayment reductions increase adherence, those effects have typically been small, in the range of 3–6 percentage points. Even among patients who had recent heart attacks and were given their cardiovascular medications for free, average adherence was only ~45%, just a few percentage points higher than that seen with regular copayments. One reason for these disappointing results is the "dog that didn't bark" problem. People who are nonadherent do not notice that their copays have been reduced because they are not using (and thus are not paying for) the service.

Indeed, one of the valuable lessons learned from efforts to introduce value-based insurance design has been a reminder of the asymmetry of the forces that surround patient engagement. Based on conventional economic thought, it might seem reasonable to assume that decreasing copayments would create effects equal and opposite to those of increasing copayments. However, behavioral economic research reveals that framing matters and that losses (in this case, higher copayments intended to reduce use) loom larger in patients' minds than gains (lowered copayments). Furthermore, people who would be deterred by higher copayments are different from people who might become adherent with lower copayments, because the first group consists of those who take their medications while the second group consists of those who do not. Behavioral economic thinking, therefore, helps to explain what has been observed: increases in copayments have larger effects in reducing adherence than decreases in copayments have in raising adherence. In general, copayment increases lead to far smaller decreases in medication adherence than copayment decreases lead to increases in medication adherence.

Value-based insurance design is an appealing idea. But its benefits could be increased through the application of ideas from behavioral economics, such as simple changes in reward delivery to increase salience (e.g., retaining the copay, but sending a rebate) and communications from insurers to patients so that even those who are nonadherent are aware of the benefit. Better designs might also reflect that most medication adherence happens at least daily, and so reinforcements to that behavior probably need to occur more frequently than the 30- or 90-day cycles coinciding with prescription refills.

A series of studies have used daily lottery-based financial incentives to improve medication adherence. Early work tested the impact of a lottery on medication adherence among patients on warfarin. Participants were eligible for the lottery daily if they correctly took their warfarin the day before. In two pilot studies, we found that the rate of incorrect pill taking was 1.6–2.3%, compared with a historic mean of 22% incorrect pill taking. In a two-arm randomized trial of lotteries for warfarin adherence, the a priori subgroup with baseline international normalized ratios (INRs) below the therapeutic range showed no change relative to control, but in the a priori subgroup with out-of-range INRs, there was a significant reduction in out-of-range INRs in the lottery arm versus the control arm (adjusted odds ratio, 0.39; 95% CI, 0.25–0.62).

A four-arm National Heart, Lung, and Blood Institute–funded randomized controlled trial tested the impact of daily lotteries and daily reminders in a 2 × 2 factorial design on warfarin adherence to address the question of the degree to which a daily lottery is effective due to the fact that it also constitutes a daily reminder. While participants in the reminder group had the lowest percentage of time out of target INR range, with an adjusted odds of an out-of-range INR 36% lower than among those in the control group (95% CI, 7–55%), the only group with significant improvement in incorrect adherence was the lottery group (incorrect adherence: 12.1% compared with 23.7% in the control group; difference of 7.4%; 95% CI, −14 to −0.3%). There was no relationship between changes in adherence and anticoagulation control in the lottery group, highlighting that participants may appear to change their behavior without perhaps taking the medication and the importance of serologic or biometric confirmation when possible.

A more recent study of 1509 patients hospitalized with heart attacks from 45 states did not find an effect of lottery incentives on time to first vascular rehospitalization (hazard ratio, 0.89; 95% CI, 0.73–10.09; $p = .27$) or death (hazard ratio, 1.04; 95% CI, 0.71–1.52; $p = .84$). Mean medical costs did not differ between control ($29,811) and intervention ($24,038) (difference, −$5773; 95% CI, −$13,682 to $2137; $p = .15$). Although it is not clear why the intervention did not succeed, it seems likely that the intervention was mistimed: patients were enrolled a mean of 40.8 days following index discharge due to the time required for adjudication of insurance claims. Post hoc analyses suggested that patients who had already been readmitted prior to joining the intervention did achieve lower subsequent readmission rates as a result of the intervention. To be successful, interventions to change behavior not only must reflect good principles of behavioral science but must also fit logistically into the information systems and patient and clinician journeys that already exist.

The 5000 Hours Problem Indeed, a major challenge is determining how to reach patients and reinforce their behavior each day if we want to significantly improve their health behaviors. Even patients with chronic illnesses may spend only a few hours a year with a doctor or nurse, but they spend ~5000 waking hours a year doing just about everything else. Those 5000 h are when they live their lives and make choices about what to eat and whether to exercise, smoke, take their medications, or visit the doctor.

Although what people do in those hours almost certainly affects their health outcomes, the hours are typically ignored by the U.S. health

care system, in part because current approaches to U.S. health care financing support health care during visits to the doctor, not between them, and because "hovering over" people during the hours between visits is personnel-intensive, often requiring nurses or other clinicians to call or visit patients or to staff telemedicine programs. Hovering also requires a fair amount of the very kind of engagement in their own health and health care that is so often missing in the patients these interventions aim to reach. As a result, many of the most promising efforts in telemedicine and home health care have been disappointing.

If some form of hovering is required to engage people who are otherwise hard to engage during the 5000 h, it almost certainly has to become substantially more automated—both because providers must reduce the need for expensive personnel and because patients have in many cases already revealed limits to their willingness to exert themselves to improve their health. Nevertheless, there is reason for optimism based on the increasing use of cell phones and other wireless devices that make it technologically easier to embed reminders and other forms of touch into patients' lives. Indeed, one key lesson from behavioral economics is that rather than trying to change people's behavior patterns to promote health, it is better to restructure their environment and circumstances so that their existing behavior patterns are more likely to lead to better outcomes. Those efforts require a substantial amount of hovering over patients. Cell phones and other wireless devices do not necessarily change behavior on their own, but because they are already part of many patients' everyday lives, they allow previously private behaviors to be witnessed and at times acted upon.

Indeed, an error in early approaches to technology and health behavior overgeneralized from the technologies that support the "quantified self" movement. Apps and wearables that track your diet, physical activity, and biometrics were largely designed for people passionate about measuring themselves. Such individuals do not need a lot of encouragement to wear devices or enter data. The same approaches are far less likely to be useful for patients with difficult-to-manage chronic illness. Many of the internal and external challenges that make their chronic illness hard to manage also make such monitoring hard to manage. A patient who is nonadherent to medication is likely also to be nonadherent to using a new electronic device, but devices like cell phones that are already in use or other devices that require much less active involvement (like wireless pill bottles) offer more conceptual appeal.

REFLECTIONS ON SARS-CoV-2

Since SARS-CoV-2 began spreading early in 2020, it has become increasingly clear that behavioral decisions among both policymakers and individuals play a major role in spread. Within countries that exercised strict control over individual behavior through measures like mandated testing, isolation, quarantine, use of contact tracing apps, and fines for noncompliance, containment was achieved and the number of new cases dropped nearly to zero. Within countries like the United States in which there was no comparable national policy and policy decisions were left to the states, the rate of spread and degree of containment varied enormously. Leaders of many states relied on the rational-world bias, assuming individual decisions would be deliberative and rational. Individual decisions about whether to maintain social distance, wear masks, and otherwise modify routines to reduce risk reflect many of the behavioral challenges described earlier in this chapter—present bias, overoptimism, anticipated regret, narrow bracketing, status quo bias, and the peanuts effect all contributed to people either taking more or less precautions depending on their personal decision-making proclivities. Vaccination acceptance poses similar challenges; if governments leave it up to individuals to decide and do not use strong incentives or mandates, significant variability in behavior will likely ensue with corresponding consequences for the populations they govern.

FUTURE PERSPECTIVES

Human health derives from the interaction of basic biologic processes, environmental exposures, social structures, and behavior. The field of behavioral economics has greatly contributed to our understanding of behavior and has made significant contributions to the science of public policy. Given that understanding, we have the opportunity to replace older policies based on unrealistic normative models of rational decision-making with newer policies reflecting our most up-to-date understanding of how humans actually make decisions. Individual and population health outcomes would be very different if people were able to weigh the present and future costs of their actions carefully and dispassionately and had the necessary information and self-control to implement behavioral plans and overcome decision errors that contribute to unhealthy behaviors. Because few people can meet any of those challenges, we should not structure our behavior change interventions and public health policies around such models of behavior.

There is broad potential for improving private and public approaches to health behavior by drawing upon a more realistic understanding of human motivation rooted in behavioral economics. One major question is whether developed economies will continue to invest the majority of their health care dollars in treatment (typically ~97% of health care dollars) rather than shifting it toward innovations that seek to keep people healthy. This will be particularly important in settings where treatment options are limited and highly effective methods of prevention exist. For example, it has been estimated that a combination of low-cost cardiovascular drugs could reduce cardiovascular events by 62–88% with perfect adherence, revealing that reducing atherosclerotic cardiovascular disease risk is largely a *behavioral* challenge, given that adherence to medications remains low despite effective pharmacologic solutions. Shifts in health care financing away from fee-for-service toward various forms of payment that require health delivery systems to take on financial risk for populations of patients may drive greater interest in addressing these behavioral and social determinants of health. Research expenditures, which in many developed countries are also roughly allocated ~97% to new treatments and ~3% to prevention, similarly could be shifted to focus more on testing of innovative approaches to improve population health.

The same errors that misdirect patients and providers also misdirect policymakers. In part because of present bias, preventive services often are covered by insurance only if they show a positive return on investment, yet treatments of existing disease are not held to the same standard. An employer wondering whether to introduce a smoking cessation program for employees wonders about the return on that investment in terms of reduced illness and its cost. The same employer might never question the return on investment of treating lung cancer in the same employee pool, despite what would almost certainly be a negative return on investment. These asymmetries are so embedded in policy making as to be nearly invisible or at least unchallengeable. In fact, the cost of treatments is not even allowed to be considered in Medicare coverage decisions. This prohibition naturally leads to overinvestment in treatments of low value and underinvestment in prevention. The same standard for assessing the impact of health programs, with the goal of achieving the most health possible with the available resources, should be used for both preventive and therapeutic services.

Despite the promise of behavioral economics in structuring policy solutions to social goals, plenty of existing policies that have nothing to do with behavioral economics are effective. For example, raising taxes on cigarettes or sugar-sweetened beverages or other unhealthy goods where it is in the public interest to consume less is a powerful policy tool derived from classical economics. Indeed, tobacco taxes represent one of the most effective ways to curb the use of tobacco and its initiation among youth. Behavioral economics can help make such policies more effective but should not be seen as a substitute for them.

For private-sector entities, the implications of choosing defaults wisely are recognized by many organizations that aim to shift the "path of least resistance" toward healthier choices. Setting up defaults in benefit program design to favor health plans that provide better coverage of preventive services, changing the environment in workplaces to make it easier to take the stairs, and serving more healthful food in cafeterias represent approaches to gently lead people toward individual and population goals.

While medical research continues to generate new tests, interventions, and drugs, all of which successfully target conditions recently

seen as intractable, even the most effective drugs will not work if physicians fail to prescribe them and if patients fail to take them. Although the dominant forms of investigation in medicine seek cellular or molecular therapeutic targets to modify disease, behavioral sciences have revealed cognitive pathways that operate nearly as predictably as the genetic code. The opportunity for behavioral economics to improve health and health care delivery derives from its recognition of these behavioral pathways and the growing empirical evidence about how to best make use of them.

482 Complementary and Integrative Therapies and Practices

Helene M. Langevin

The search for health and improved well-being includes many treatments, practices, and systems of care that may have originated outside conventional medicine but are gradually being folded into mainstream health care. The current health care system is fragmented, often emphasizing the pharmacologic treatment of disease alone, while often neglecting the promotion, support, and, importantly, restoration of health. Though the disease-focused model is dominant in our research and health care ecosystem, there has been a longstanding awareness that many chronic diseases, including pain conditions, can be prevented or better managed by incorporating nonpharmacologic interventions such as nutrition, exercise, and stress management into care, with an emphasis on understanding the person as a whole. Many complementary practices follow this model, and there is preliminary evidence indicating that these approaches lead to improved self-care, a better personal sense of well-being, and a greater commitment to a healthy lifestyle. Integrative health emphasizes not only the integration of complementary and conventional care but also an integrative approach to treatment of the whole person. This includes expanding our understanding of how physiologic systems interact with one another and of the connections between physical, psychological, and social aspects of health. Integrative health also includes striving for a better understanding of "salutogenesis" or pathogenesis in reverse, meaning the process by which health is restored when recovering from an injury, acute illness, or the exacerbation of a chronic disease, or when a "predisease" condition such as prediabetes or prehypertension is reversed through changes in behavior rather than pharmacologic treatment.

DEFINITIONS AND SCOPE

Complementary health therapies and practices include a broad range of practices, interventions, and natural products that are not typically part of conventional medical care **(Table 482-1)**. The term *complementary* refers to the use of these practices together with conventional therapies and is increasingly preferred to the term *alternative*, which denotes usage as a substitute for standard care.

The term *integrative health care* refers to conventional and complementary therapies and practices used together in a coordinated way. Integrative health also emphasizes care of the whole person that aims to improve health in multiple interconnected domains: social, psychological, and physical, including multiple organs and systems.

The use of integrative approaches to health and wellness has grown within care settings across the United States. Researchers are currently exploring the potential benefits of integrative health in a variety of situations, including pain management for military personnel and veterans, relief of symptoms in cancer patients and survivors, and programs to promote healthy behaviors.

Although complementary therapies and practices vary widely, it is useful to classify them by their primary therapeutic input, which may be dietary (e.g., diet, herbs), psychological (e.g., meditation), physical (e.g., massage, acupuncture), or the combination of psychological and physical (e.g., yoga, tai chi). Although some complementary health practices are recommended or provided by a physician or a complementary health care provider such as a chiropractor, acupuncturist, or naturopathic practitioner, many of these practices are undertaken as "self-care." Although some are reimbursed, most are paid for out of pocket.

PATTERNS OF USE

The first large survey of use of complementary health practices was performed by David Eisenberg and associates in 1993. It surprised the medical community by showing that >30% of Americans use complementary health products and practices. Many surveys since that time have extended those conclusions. The National Health Interview Survey (NHIS), a large, national household survey in which thousands of Americans are interviewed about their health- and illness-related experiences, is conducted annually by the National Center for Health Statistics, a component of the Centers for Disease Control and Prevention. This survey, which addressed the use of complementary health practices in 2002, 2007, 2012, and 2017, uses methods that create a nationally representative sample and has a sample size large enough to permit valid estimates about some subgroups. Information was obtained from 34,500 adults and 10,200 children in 2012 and 61,267 adults in 2017.*

In the first three surveys, approximately one-third of adults reported using some form of complementary therapy or health practice. In the 2012 survey, 32.2% of adults and 11.6% of children had used one or more modalities. These surveys yielded the estimate that nonvitamin, nonmineral dietary supplements are used by ~18% of adults and 5% of children. To identify trends in Americans' use of specific practices, the 2017 survey data were compared with a version of the survey fielded

*Information on the use of complementary health approaches was collected from a sample of adults aged 18 and over who participated in the 2012 (n = 34,525) and 2017 (n = 26,742) NHIS of adult alternative medicine or complementary health supplements, respectively.

TABLE 482-1 Glossary of Complementary and Integrative Health Therapies and Practices	
Acupuncture	A family of procedures involving stimulation of defined anatomic points, a component of the major Asian medical traditions; most common application involves penetrating the skin with thin, solid, metallic needles that are manipulated by the hands or by electrical stimulation
Ayurvedic medicine	The major East Indian traditional medicine system; treatment combines products (mainly derived from plants, but may also include animal, metal, and mineral), diet, exercise, and lifestyle
Biofeedback	The use of electronic devices to help people learn to consciously control body functions such as breathing or heart rate
Chiropractic	Chiropractic care involves the adjustment of the spine and joints to influence the body's nervous system and natural defense mechanisms to alleviate pain and improve general health; primarily used to treat back problems, headaches, nerve inflammation, muscle spasms, and other injuries and traumas
Dietary supplement	A product that is intended to supplement the diet, is taken by mouth, contains one or more dietary ingredients (including vitamins, minerals, herbs, amino acids, or certain other substances), and is labeled as being a dietary supplement
Homeopathy	A medical system with origins in Germany that is based on a core belief in the theory of "like cures like"—compounds that produce certain syndromes, if administered in very diluted solutions, will be curative
Hypnosis	The induction of an altered state of consciousness characterized by increased responsiveness to suggestion
Massage	Manual therapies that manipulate muscle and connective tissues to enhance the function of those tissues and promote muscle relaxation and well-being
Meditation	A group of practices, largely based in Eastern spiritual traditions, intended to focus or control attention and obtain greater awareness of the present moment, or mindfulness
Mind and body practices	A large and diverse group of procedures or techniques that are administered or taught by a trained practitioner or teacher; examples include acupuncture, massage therapy, meditation, relaxation techniques, spinal manipulation, tai chi, and yoga
Natural products	A variety of products such as herbs (also known as botanicals), vitamins and minerals, and probiotics, which are widely marketed, readily available to consumers, and often sold as dietary supplements
Naturopathy	A clinical discipline that emphasizes a holistic approach to the patient, herbal medications, diet, and exercise; practitioners have degrees as doctors of naturopathy
Osteopathy	A clinical discipline, now incorporated into mainstream medicine, that historically emphasized spinal manipulative techniques to relieve pain, restore function, and promote overall health
Relaxation techniques	A number of practices such as progressive relaxation, guided imagery, biofeedback, self-hypnosis, and deep breathing exercises, with the goal of producing the body's natural relaxation response, characterized by slower breathing, lower blood pressure, and a feeling of increased well-being
Spinal manipulation, osteopathic manipulation	A technique where practitioners use their hands or a device to apply a controlled thrust (i.e., a force of a specific magnitude or degree in a specific direction) to a joint of the spine
Tai chi	A mind and body practice originating in China that involves slow, gentle movements and sometimes is described as "moving meditation"
Traditional Chinese medicine	A medical system that uses acupuncture, herbal mixtures, massage, exercise, and diet

in 2012. Yoga was the most commonly used complementary health approach among U.S. adults in 2012 (9.5%) and 2017 (14.3%). The use of meditation increased more than threefold from 4.1% in 2012 to 14.2% in 2017. The percentage of children aged 4–17 years who used yoga in the previous 12 months increased significantly from 3.1% in 2012 to 8.4% in 2017. Meditation increased significantly from 0.6% in 2012 to 5.4% in 2017.

Americans are willing to pay for complementary health products and practices; the estimated out-of-pocket expenditure for complementary health practices in 2012 was $30.2 billion ($28.3 billion for adults and $1.9 billion for children), representing 1.1% of total health expenditures and 9.2% of out-of-pocket costs. On visits to complementary practitioners, Americans spent $14.7 billion out of pocket, which is almost 30% of what they spent out of pocket on services by conventional physicians ($49.6 billion). On natural products, such as dietary supplements, Americans spent $12.8 billion out of pocket, which was about one-quarter (24%) of what they spent out of pocket on prescription drugs ($54.1 billion).

According to the NHIS surveys, painful conditions are the most common reasons why American adults use complementary health products and practices. About 40 million American adults experience severe pain in any given year, and they spend >$14 billion out of pocket on complementary therapies to manage their pain. In one analysis of data from the 2012 NHIS survey, >40% of people with a musculoskeletal pain disorder used a complementary health approach. This was significantly higher than use by people without a musculoskeletal pain disorder (24%). Many complementary and integrative health interventions are multimodal in nature and may contribute to pain relief by impacting several pain processes simultaneously and addressing the cognitive, emotional, and physical complexities associated with pain.

Some patients seek out complementary health practitioners because they offer optimism or greater personal attention. For others, therapies and practices perceived as outside the mainstream reflect a "self-help" approach to health and wellness or satisfy a search for "natural" or less invasive alternatives. Since dietary supplements are labeled as "natural," they are often believed, incorrectly, to be inherently healthy.

CATEGORIES OF COMPLEMENTARY AND INTEGRATIVE HEALTH THERAPIES AND PRACTICES BASED ON PRIMARY THERAPEUTIC INPUT

PRIMARY DIETARY INPUT

Natural products, including plant and animal products, have a long and impressive history as sources of medicine and as important resources for biologic research. Whether as herbal supplements or as part of a diet, natural products are frequently consumed as a complex mixture. This complexity is further amplified by potential interactions with endogenous metabolic pathways, including those associated with the microbiome. The result is a collection of natural products and their metabolites that, individually and/or collectively, are associated with a network of biologic activity. Importantly, in addition to direct action on biologic targets, the activity of natural products can be influenced by an individual's health and metagenomic background. Although much remains to be understood about mechanisms of action, results of research on some natural products for a few conditions appear promising.

Pain Recent research to identify new sources of medicine based on natural products has yielded beneficial tools for probing the molecular features of pain pathways. Since the early days of pharmacology, natural products such as the opium poppy and capsaicin have provided

important insights into the molecular basis of pain sensation. Coupled with human genetics, preclinical animal models, and clinical pharmacology, natural product research is continuing to help validate new targets for pain relief. Resiniferatoxin (RTX), produced by euphorbias, is effective as a long-duration, nonopioid, single-administration treatment for bone cancer pain. In recent laboratory studies, conolidine, derived from *Tabernaemontana divaricata*, appears to have analgesic properties; however, its mechanism of action remains unclear. Two compounds in kratom (*Mitragyna speciosa*) leaves, mitragynine and 7-hydroxymitragynine, interact with opioid receptors in the brain, decreasing pain when taken in high doses; however, to date, there are no clinical trials to evaluate the health effects of kratom or to determine if kratom is an effective or safe treatment for any pain condition or for opioid addiction. Other research is examining the potentially valuable effects of botulinum toxin, asymptomatic bacteriuria (ASB) strains of *Escherichia coli*, snail venom, and the vitamin B isoform nicotinamide riboside on pain. There is also some evidence that devil's claw (*Harpagophytum procumbens*) may be helpful for low-back pain over the short term. An increasing amount of attention has been given recently to the nonpsychogenic effects of cannabinoids, such as cannabidiol (CBD), and terpenes found in the cannabis plant on chronic pain, particularly neuropathic pain; studies have found low- to moderate-quality evidence that these medicines produced better pain relief than placebos.

Anxiety Some research suggests that a chamomile extract may be helpful for generalized anxiety disorder, but the studies are preliminary, and their findings are not conclusive. Melatonin may help reduce anxiety in patients who are about to have surgery and may be as effective as standard treatment with midazolam in reducing preoperative anxiety.

Rheumatoid Arthritis Clinical trials on rheumatoid arthritis (RA) have found that fish oil supplements can help alleviate tender joints and morning stiffness and reduce the daily nonsteroidal anti-inflammatory drug (NSAID) requirement of RA patients. Gamma-linolenic acid (GLA) is an omega-6 fatty acid found in the oils from some plants, including evening primrose (*Oenothera biennis*), borage (*Borago officinalis*), and black currant (*Ribes nigrum*). Oils containing GLA may have some benefit in relieving RA symptoms; however, only a few studies have been conducted on each of the oils. Thunder god vine (*Tripterygium wilfordii*), an herb used in traditional Chinese medicine, may improve some RA symptoms, but there have been only a few high-quality studies for this condition.

Irritable Bowel Syndrome There is some evidence that enteric-coated peppermint oil capsules are modestly efficacious, in the short-term, in reducing several common symptoms of irritable bowel syndrome (IBS), in particular abdominal pain, bloating, and gas. Long-term efficacy has not been established. Probiotics may improve symptoms of IBS; however, benefits have not been conclusively demonstrated, and not all probiotics have the same effects.

Depression At present, it is uncertain whether omega-3 fatty acid supplementation is useful for depression. Some studies have shown small effects in adjunctive therapy in patients with a diagnosis of major depressive disorder (MDD) and in depressive patients without a diagnosis of MDD; however, most trials have been adjunctive studies. Controlled trials of omega-3 fatty acids as monotherapy are inconclusive compared to standard antidepressant medicines, and it remains unclear whether a mechanism is present to suggest that a pharmacologic or biologic antidepressant effect exists. Results of some studies suggest that St. John's wort (*Hypericum perforatum*) may have an effect on mild to moderate MDD for a limited number of patients, similar to standard antidepressants, but the evidence is far from definitive. Although some studies have demonstrated a slight efficacy over placebo, others contradict these findings.

Smoking Cessation The natural product cytisine, primarily used in Central and Eastern European countries for smoking cessation, is not currently approved by the U.S. Food and Drug Administration (FDA) but is undergoing testing in the United States.

Eye Disease Findings from the Age-Related Eye Disease Studies (AREDS and AREDS2) suggest that dietary supplementation with antioxidant vitamins and zinc may slow the progression of age-related macular degeneration (AMD) in people who have intermediate AMD and those who have late AMD in one eye. The AREDS2 trial found that adding lutein and zeaxanthin or omega-3 fatty acids to the original AREDS formulation (with beta-carotene) had no overall effect on the risk of late AMD. However, the trial also found that replacing beta-carotene with a 5-to-1 mixture of lutein and zeaxanthin helped further reduce the risk of late AMD.

Multiple Sclerosis Orally administered cannabinoids (cannabis extract, synthetic tetrahydrocannabinol [THC]), mucosally delivered cannabinoids (cannabis THC and CBD extract oral spray, nabiximols [trade name Sativex]), and smoked cannabis have all been studied for therapeutic effects in multiple sclerosis (MS). Based on available evidence, cannabinoids may relieve spasticity and/or pain in people with MS; however, no marijuana-derived medications are approved by the FDA to treat MS. Sativex, an oral mucosal spray containing a mixture of THC and CBD, has received regulatory approval in >25 countries outside the United States for the treatment of spasticity (muscle stiffness/spasm) due to MS. Sativex is currently licensed in the United Kingdom for use as an add-on treatment for MS-related spasticity when people have shown inadequate response to other symptomatic treatments. Importantly, the psychoactive properties and other potential adverse effects of preparations containing cannabinoids need to be considered, including interactions with other medications and natural products; more research is needed in this area.

Other Conditions There has been limited research on various natural products for several other conditions such as attention-deficit/hyperactivity disorder, hypercholesterolemia, seasonal affective disorder, and psoriasis, but no definitive conclusions about efficacy can be drawn.

General Health and Wellness In the 2012 NHIS, users of natural product supplements were twice as likely to report taking the natural product for a wellness reason than for treatment of a specific health condition (88.9 vs 44.9%, respectively). Although to date, research on natural products has focused on their use for specific diseases as outlined above, a better understanding is needed about how natural products, including food, can be used most effectively to support health.

Challenges One challenge in this area is the extremely varied doses of natural products that are sold over the counter and used without much guidance or evidence of efficacy. We also know from research on vitamins that "more is not necessarily better" and that taking a "natural" substance such as a vitamin in quantities that greatly exceed what is found in food can be harmful.

Additional challenges in the assessment of plant products include their complexity and variability, including possible instability of active components or the presence of impurities, conflicting or unreliable conclusions in the literature, and low statistical power of studies. Further, there is a paucity of data on the safety of many products, including the safety of their use in a twenty first century context (e.g., if taken with modern prescription drugs) and their appropriate use in the context of traditional or indigenous practices.

Regulation There is an important distinction between natural products sold as dietary supplements and drugs developed from natural sources that are used to treat specific diseases. The Dietary Supplement Health and Education Act (DSHEA), passed in 1994, gives authority to the FDA to regulate dietary supplements, but with expectations that differ in many respects from the regulation of drugs or food additives. Purveyors of dietary supplements cannot claim that they prevent or treat any disease. They can, however, claim that they maintain "normal structure and function" of body systems. For example, a product cannot claim to treat arthritis, but it can claim to maintain "normal joint health."

Homeopathic products predate FDA drug regulations and are sold with no requirement that they be proved effective. Although

homeopathic products are widely believed to be safe because they are highly dilute, one product, a nasal spray called Zicam, was withdrawn from the market when it was found to produce anosmia, probably because of significant zinc content. In January 2017, the FDA warned consumers about homeopathic teething tablets containing belladonna that pose a serious risk to infants and children.

Regulation of advertising and marketing claims is the purview of the Federal Trade Commission (FTC). The FTC does take legal action against promoters or websites that advertise or sell dietary supplements with false or deceptive statements. Misleading marketing of dietary supplements, homeopathic products, and indeed other complementary health products and practices contributes to the very significant risk that individuals will use them instead of effective conventional modalities. For example, in April 2020, the FTC sent warning letters to several companies allegedly selling unapproved products—some of which included high-dose dietary supplements—that may violate federal law by making deceptive or scientifically unsupported claims about their ability to treat or cure COVID-19.

Inherent Toxicity Although the public may believe that "natural" equates with "safe," it is abundantly clear that natural products can be toxic. Misidentification of medicinal mushrooms has led to liver failure. Contamination of tryptophan supplements caused the eosinophilia-myalgia syndrome. Herbal products containing particular species of *Aristolochia* were associated with genitourinary malignancies and interstitial nephritis. In 2013, dietary supplements containing 1,3-dimethylamylamine (DMAA), often touted as a "natural" stimulant, led to cardiovascular problems, including heart attacks. Among the most controversial dietary supplements is *Ephedra sinica*, or ma huang, a product used in traditional Chinese medicine for short-term treatment of asthma and bronchial congestion. The scientific basis for these indications was revealed when ephedra was shown to contain ephedrine alkaloids, especially ephedrine and pseudoephedrine. With the promulgation of the DSHEA regulations, supplements containing ephedra and herbs rich in caffeine sold widely in the U.S. marketplace because of their claims to promote weight loss and enhance athletic performance. Reports of severe and fatal adverse events associated with use of ephedra-containing products led to an evidence-based review of the data surrounding them, and in 2004, the FDA banned their sale in the United States.

A major current concern with dietary supplements is adulteration with pharmacologically active compounds. Multi-ingredient products marketed for weight loss, bodybuilding, "sexual health," and athletic performance are of particular concern. Recent FDA recalls have involved contamination with steroids, diuretics, stimulants, and phosphodiesterase type 5 inhibitors.

Herb-Drug Interactions A number of natural products have potential impacts on the metabolism of drugs. This effect was illustrated most compellingly with the demonstration in 2000 that consumption of St. John's wort interferes with the bioavailability of the HIV protease inhibitor indinavir. Later studies showed its similar interference with metabolism of topoisomerase inhibitors such as irinotecan, with cyclosporine, and with many other drugs. The breadth of interference stems from the ability of hyperforin in St. John's wort to upregulate expression of the pregnane X receptor, a promiscuous nuclear regulatory factor that promotes the expression of many hepatic oxidative, conjugative, and efflux enzymes involved in drug and food metabolism.

Because of the large number of compounds that alter drug metabolism and the large number of agents some patients are taking, identification of all potential interactions can be a daunting task. Several useful Web resources are available as information sources **(Table 482-2)**. Clearly, attention to this problem is particularly important with drugs with a narrow therapeutic index, such as anticoagulants, antiseizure medications, antibiotics, immunosuppressants, and cancer chemotherapeutic agents. Although there are many examples of substances of natural origin successfully used as pharmaceutical drugs, in general, natural products ingested as food, rather than concentrated extracts, are less likely to cause harm.

PRIMARY PSYCHOLOGICAL AND PHYSICAL INPUT

"Mind and body" practices and disciplines consist of physical procedures or exercises, manual therapies, or mental techniques that are administered or taught by a clinician, trained practitioner, or teacher. Examples include acupuncture, massage therapy, meditation, relaxation techniques, spinal manipulation, and yoga. These practices are being used with increasing frequency in mainstream health care facilities for both patients and health care providers. The evidence base for the effectiveness of mind and body practices is still relatively incomplete, but a few rigorous examples where there is promise of usefulness and safety include acupuncture and tai chi for pain associated with osteoarthritis (OA) of the knee; tai chi for fibromyalgia; mindfulness meditation for anxiety-related symptoms; relaxation techniques for acute stress disorder or posttraumatic stress disorder (PTSD) and headaches and migraine; yoga for fatigue and sleep disturbances, depression and anxiety, and quality of life of breast cancer patients; and acupuncture, massage, yoga, and spinal manipulation for chronic back pain. New research is shedding light on the effects of meditation and acupuncture on central mechanisms of pain processing and perception and the regulation of emotion and attention. Although many unanswered questions remain about these effects, findings are pointing to scientifically plausible mechanisms by which these modalities might yield benefit.

Primary Psychological Input For some mind and body therapies and practices, the primary therapeutic input is predominantly mental. This category includes conventional types of psychotherapy, such as cognitive behavioral therapy (CBT), and complementary practices, such as meditation and mindfulness-based stress reduction (MBSR). Relaxation techniques, including biofeedback-assisted relaxation, also fall into this category. The boundary between conventional and complementary can be blurred, as CBT programs, for example, frequently incorporate elements of MBSR and relaxation techniques. These therapies and practices are being gradually integrated into aspects of conventional care, such as cardiac rehabilitation programs, and are playing an increasingly recognized role in the management of pain, as well as stress and sleep disturbances.

PAIN Mindfulness meditation has been found to significantly reduce pain in experimental and clinical settings and to improve a wide spectrum of clinically relevant cognitive and health outcomes, including for low-back pain and fibromyalgia. It is unclear if the analgesic mechanisms supporting mindfulness meditation are distinct from or parallel to those engaged by placebo and/or slow, rhythmic breathing; however, there is emerging evidence suggesting that mindfulness meditation engages multiple unique neural mechanisms not mediated by endogenous opioids to reduce pain. In addition, findings from a few studies have demonstrated that training patients in the use of self-hypnosis significantly reduced their need for sedatives and

analgesia when undergoing interventional radiologic procedures. The efficacy of biofeedback has been evaluated in numerous studies for tension headaches, with positive results. Several studies have shown that biofeedback decreased the frequency of both pediatric and adult migraines, with some showing an effect lasting over an average follow-up phase of 17 months.

SLEEP DISORDERS The American College of Physicians practice guidelines (2016) strongly recommend the use of CBT for insomnia (also called CBT-I) as the initial treatment for chronic insomnia. Although CBT-I often includes relaxation techniques, it is not clear whether relaxation alone is beneficial.

ANXIETY AND STRESS-RELATED DISORDERS Meditation therapy is commonly used and has been shown to be of small to modest benefit for people with anxiety-related symptoms. There is some evidence that transcendental meditation may have a beneficial effect on anxiety. However, there is a lack of studies with adequate statistical power in patients with clinically diagnosed anxiety disorders, which makes it difficult to draw firm conclusions about its efficacy in this context. Relaxation techniques may be helpful in managing a variety of stress-related health conditions, including anxiety associated with ongoing health problems and in those who are having medical procedures. Some studies also have suggested that hypnosis may be helpful for anxiety and health-related quality of life in people with IBS. Evidence suggests that relaxation techniques may also provide some benefit for symptoms of PTSD and may help reduce occupational stress in health care workers. For some of these conditions, relaxation techniques are used as an adjunct to other forms of treatment.

MENOPAUSAL SYMPTOMS There is some evidence suggesting that hypnosis may help improve certain menopausal symptoms, such as hot flashes.

SUBSTANCE USE DISORDERS There is some evidence to suggest that hypnotherapy may improve smoking cessation, but data are not definitive. Available data suggest that mindfulness-based interventions may help significantly reduce the consumption of several substances including alcohol, cigarettes, opiates, and others compared to control groups; however, many studies have had small sample sizes, methodologic problems, and a lack of consistently replicated findings.

Primary Physical Input For another group of mind and body interventions, the primary therapeutic input is predominantly physical. The physical input can be delivered manually (e.g., massage) or using a device (e.g., acupuncture) or can be generated by the patient (e.g., exercise).

PAIN The role of acupuncture in pain management has been controversial for decades, with critics pointing out its "prescientific" theoretical basis, and indeed, the rationale for the use of specific "acupuncture points" remains to be established. However, recent large-scale meta-analyses have demonstrated acupuncture to be superior to both usual care and sham acupuncture for chronic musculoskeletal pain, headache, and OA, with beneficial treatment effects persisting for up to 12 months. The most recent (2017) American College of Physicians clinical guidelines recommend acupuncture as one of the initial treatment options for patients with acute, subacute, and chronic low-back pain. The role of both osteopathic and chiropractic spinal manipulative therapies (SMTs) in management of low-back pain also has been the subject of a number of carefully performed trials and many systematic reviews. Conclusions are not consistent, but the American College of Physicians guidelines conclude that spinal manipulation has a small effect on improving function and pain compared with control—either a sham manipulation or an inert treatment. Although evidence for spinal manipulation for chronic low-back pain is graded as *low quality*, the recommendation for consideration of nonpharmacologic treatment including spinal manipulation is graded as a *strong recommendation*, reflecting increasing concern with the impact of chronic opioid use for low-back pain. The evidence of benefit of spinal manipulation for neck pain is not as extensive, and continued concern that cervical manipulation may occasionally precipitate vascular injury clouds a contentious debate. Low- to moderate-quality evidence suggests that massage therapy is superior to nonactive therapies in reducing arthritis pain and improving functional outcomes. Massage may provide short-term relief from low-back pain, but the evidence is not of high quality. There is some evidence that massage has a positive effect on migraine, tension headaches, and neck pain.

DEPRESSION Acupuncture may provide a modest reduction in symptoms of depression, particularly when compared with no treatment or a control.

CANCER SYMPTOMS AND TREATMENT SIDE EFFECTS Acupuncture or electroacupuncture may be an appropriate addition to drug treatment for managing treatment-related nausea and vomiting in patients with cancer.

SEASONAL ALLERGIES Acupuncture may relieve symptoms of allergic rhinitis. Clinical practice guidelines from the American Academy of Otolaryngology–Head and Neck Surgery include acupuncture among the options that health care providers may offer to interested patients with allergic rhinitis.

Combined Psychological and Physical Input The primary therapeutic input for other mind and body practices is a combination of physical and psychological. Examples of practices in this category include yoga and tai chi, which combine movement, physical postures, and meditation.

PAIN Yoga and tai chi can be beneficial for patients with fibromyalgia or chronic low-back pain, and yoga compared to nonexercise controls results in small to moderate improvements in back-related function at 3 and 6 months. Some studies have demonstrated that tai chi produces beneficial effects similar to those of standard physical therapy in the treatment of knee OA. Regular yoga training may be helpful in reducing knee arthritis symptoms in patients with OA or RA.

MOTOR FUNCTION Tai chi has been shown to improve overall motor function, including balance and stability in older adults.

GENERAL WELLNESS Yoga may benefit people's general wellness by relieving stress, supporting good health habits, and improving mental/emotional health and sleep. Yoga may also help with quitting smoking, anxiety or depressive symptoms associated with difficult life situations, and quality of life for people with chronic diseases. Tai chi also may also improve quality of life in people with heart disease, cancer, and other chronic illnesses.

MULTIMODAL THERAPIES AND SYSTEMS

Multimodal approaches to health comprise two or more interventions such as conventional medicine, lifestyle changes, physical rehabilitation, psychology, and complementary health practices in various combinations, with an emphasis on whole-person health. Complementary health therapies and practices are often multimodal in nature, both in traditional health systems (e.g., traditional Chinese medicine, naturopathy) and in modern integrative practice. The U.S. Veterans Health Administration uses a multimodal model of pain care that emphasizes nonpharmacologic methods, both conventional (e.g., physical therapy, CBT) and complementary (e.g., yoga, acupuncture), and may also include nutrition consultations. Several medical systems, such as chiropractic, osteopathy, naturopathy, and homeopathy, that arose in the late nineteenth century continue to be practiced today. Osteopathic medicine is mostly integrated into conventional medicine, while homeopathy and naturopathy have remained largely separate from mainstream medicine. Chiropractic care is increasingly available in some conventional care settings. A number of multimodal systems, often called "whole health" systems, such as traditional Chinese medicine, Ayurveda, and homeopathy, use a diagnostic and therapeutic framework that is different from that of conventional medicine, which has posed additional challenges to their rigorous investigation.

NATUROPATHY

Naturopathy, or naturopathic medicine, is a multimodal therapeutic system based on philosophical principles that guide practice.

Naturopaths prescribe conventional and unconventional diagnostic tests and medications, with an emphasis on relatively low doses of drugs, herbal medicines, healthy diet, and exercise.

CHIROPRACTIC

The practice of chiropractic care, founded by David Palmer in 1895, is the most widespread practitioner-based complementary health practice in the United States. Although the scope of practice varies widely, chiropractic practice emphasizes manual therapies for treatment of musculoskeletal complaints.

OSTEOPATHIC MEDICINE

Founded in 1892 by the physician Andrew Taylor Still, osteopathic medicine was originally based on the belief that manipulation of soft tissue and bone can correct a wide range of diseases of the musculoskeletal and other organ systems. Over the ensuing century, the osteopathic profession has welcomed increasing integration with conventional medicine. Today, the postgraduate training, practice, credentialing, and licensure of osteopathic physicians are virtually indistinguishable from those of allopathic physicians. Osteopathic medical schools, however, include training in manual therapies, particularly spinal manipulation, as well as diagnostic methods based on palpation of musculoskeletal tissues that are not part of conventional medical education.

HOMEOPATHY

The theoretical framework of homeopathy is based on two unconventional principles: "like cures like," the notion that a disease can be cured by a substance that produces similar symptoms in healthy people; and the "law of minimum dose," the notion that the lower the dose of the medication, the greater its effectiveness. Although the current lack of biologic underpinning for these principles has seriously limited the rationale for their use, the diagnostic framework of homeopathy could be the source of new insights that could be explored. As discussed previously, the regulatory framework for homeopathic remedies differs from that for dietary supplements. Homeopathic remedies are widely available and commonly recommended by naturopathic physicians, chiropractors, and other licensed and unlicensed practitioners.

RESEARCH CHALLENGES

Classic randomized controlled trial (RCT) designs may not be well suited for research on multimodal complementary interventions and systems such as naturopathy and Ayurvedic medicine. The dynamic relationships among an array of factors that affect health and wellness is inherent to the philosophy of these systems of care and poses methodologic challenges to the effective application of conventional RCT design. Pragmatic comparative effectiveness designs with "usual care" comparators are widely used to study these types of interventions, and trials may need to take into account the individualization of interventions and the underlying theories of these multimodal systems. Thus, a key component of research on multimodal therapeutic systems is the development of validated and reproducible "manualized" treatment protocols allowing for some flexibility and individual patient care. Pragmatic studies that compare multimodal treatments with usual care cannot determine which treatment components are responsible for benefits, but other kinds of translational studies can address this issue.

THERAPEUTIC OUTPUT—SYSTEMS IMPACTED AND CHALLENGES OF MECHANISTIC RESEARCH

Complementary and integrative interventions whose therapeutic input is dietary, psychological, and/or physical may exert their effects, or therapeutic output, through a variety of mechanisms and physiologic systems. For example, peppermint oil may relieve pain associated with IBS by directly relaxing gastrointestinal smooth muscle, probiotics may have effects on the nervous system as well as the gut, and some components of traditional Chinese medicine, as well as omega-3 fatty acids and their derivatives, have immune-mediated anti-inflammatory effects. Multimodal interventions with psychological and/or physical therapeutic input such as meditation and acupuncture can have effects on the nervous system and may also target other body systems affected by the pain condition; for example, tai chi may improve balance and stability by increasing flexibility and core strength, and the stretching involved in yoga may improve low-back pain by reducing connective tissue inflammation. For all types of therapeutic input, biopsychosocial interactions also may be important; for example, participation in an integrative group therapy pain management program may provide tools to help relieve symptoms of anxiety and depression as well as pain.

Deepening the scientific understanding of the connections that exist across domains of human health is important to better understand how conditions interrelate, identify multimodal interventions that address these problems, and increase the support of patients through the full continuum of their health experience, including the return to health. Studies of multimodal interventions often require multidisciplinary expertise and use state-of-the-art techniques in areas such as neuroscience, immunology, pharmacognosy, proteomics, genetics, and epigenomics. Further, there are limited preclinical models for some complementary health interventions (e.g., no relevant model for meditative movement practices such as yoga or tai chi). Objective, validated measurement tools are essential, as are processes and procedures to ensure quality control, whether the intervention is a mind and body practice or a natural product.

PATIENT AND PROVIDER RESOURCES

Physicians regularly face difficult challenges in providing patients with advice and education about complementary health therapies and practices. Of particular concern to all physicians are practices of uncertain safety and practices that raise inappropriate hopes. Cancer therapies, antiaging regimens, weight-loss programs, and products that claim to improve sexual function or athletic performance are frequently targeted for excessive claims and irresponsible marketing. A number of Internet resources provide critical tools for patient education **(Table 482-3)**. Because many complementary health products

and practices are used as self-care and because many patients research these interventions extensively on the Internet, directing patients to responsible websites can often be very helpful.

The scientific evidence regarding complementary therapies is fragmentary and incomplete. Nonetheless, in some areas, particularly pain management, it is increasingly possible to perform the kind of rigorous systematic reviews of complementary health therapies and practices that are the cornerstone of evidence-based medicine. A particularly valuable resource in this respect is the Cochrane Collaboration, which has performed >300 systematic reviews of complementary health practices. Practitioners will find this a valuable resource to answer patient questions. Practice guidelines, particularly for pain management, are also available from several professional organizations. Links to these resources are provided in Table 482-3.

SUMMARY

The frequent use of complementary and integrative health therapies and practices reflects an active interest among the public in improving health and well-being of the whole person. The current health care system is fragmented, with diseases and comorbid conditions mostly treated separately, sometimes with drugs that interact with one another. An important step in whole-person health care is considering health and disease not as separate states but as a bidirectional continuum and understanding how complementary and integrative therapies and practices, which are often multimodal in nature, consider a patient's long-term recovery and overall health.

483 The Role of Epigenetics in Disease and Treatment

Brian C. Capell, Shelley L. Berger

The term *epigenetics* was coined by Conrad Waddington in 1942, as he sought to explain how changes in phenotype could occur throughout development independent of any changes to genotype. Appending the prefix *epi-* (Greek, meaning "over, outside of, around") to genetics aptly describes the numerous mechanisms by which gene expression and phenotypes are influenced—and sometimes even inherited through cell division—independent of any changes to the underlying DNA sequence. Today, epigenetics occupies one of the most exciting topics in biology and medicine, offering profound opportunities for discovery, as well as promise for the development of new therapies for disease. Interdisciplinary by nature, the field crosses virtually all areas of science and medicine: chemistry and genetics, development and differentiation, immunology, cancer, aging, and neuroscience.

The continuous introduction of ever more powerful technologies for interrogating the epigenome has led epigenetics to become one of the most innovative fields within the biomedical sciences. Given the vast expanse of the topic and limitations of space, in this chapter, we provide a broad but brief overview of the field and then highlight key areas across the landscape of biomedicine where epigenetics has been revealed to play critical roles in physiology and disease, and importantly, where epigenetics-based therapies have demonstrated success in clinical medicine.

THE BIOCHEMICAL BASES OF EPIGENETICS

Fundamental to epigenetic regulation is the intricate organization into chromatin of each cell's genome **(Chap. 466)**. The fundamental unit of the packaging into chromatin is the nucleosome, consisting of 147 base pairs of DNA wrapped around an octamer of 8 histone proteins (two copies of each of the four core histone proteins: H2A, H2B, H3, and H4), and nucleosome assembly into a regular repeating spaced array along the DNA polymer. The presence of nucleosomes and level of compaction of this basic chromatin array determine the accessibility of the DNA strand to transcription factors, to DNA repair machinery, and to other DNA-binding entities. Thus, compaction has a profound influence on gene expression levels and on local DNA mutation rates. Open regions of chromatin (euchromatin) tend to be transcriptionally active, whereas compacted chromatin (heterochromatin) tends to be transcriptionally repressed. Higher order three-dimensional chromatin architecture such as folding and looping further contribute to epigenetic gene regulation and cellular phenotypes.

Histones include the four core histones, which are the most abundant and most frequently found throughout the genome, and the variant histones of H2A, H2B, and H3. The individual protein structures of both core and variant histones include amino- and carboxyl-terminal "tails," which are extended and unstructured, and highly conserved globular domains. The x-ray crystal structure of the nucleosome particle has illuminated the dynamic alterations of chromatin by an astonishing range of regulatory mechanisms, summarized below.

The three main processes that regulate chromatin compaction, and thus access to the DNA template, include direct methylation modifications (and oxidized derivatives of methylation) of the DNA strand itself, posttranslational modifications of histones, and remodeling of nucleosomes to alter their location and composition with variant histones **(Fig. 483-1)**. The major modification of DNA is cytosine methylation of CpG dinucleotides (5-mC), associated with gene repression and catalyzed by the DNMT1, DNMT3A, and DNMT3B enzymes. DNMT3A and 3B catalyze the addition of methyl groups on unmethylated DNA de novo at CpG dinucleotides that are typically located throughout transcribed genes and in intergenic regions, but lacking at promoters, while DNMT1 is critical for the maintenance of the

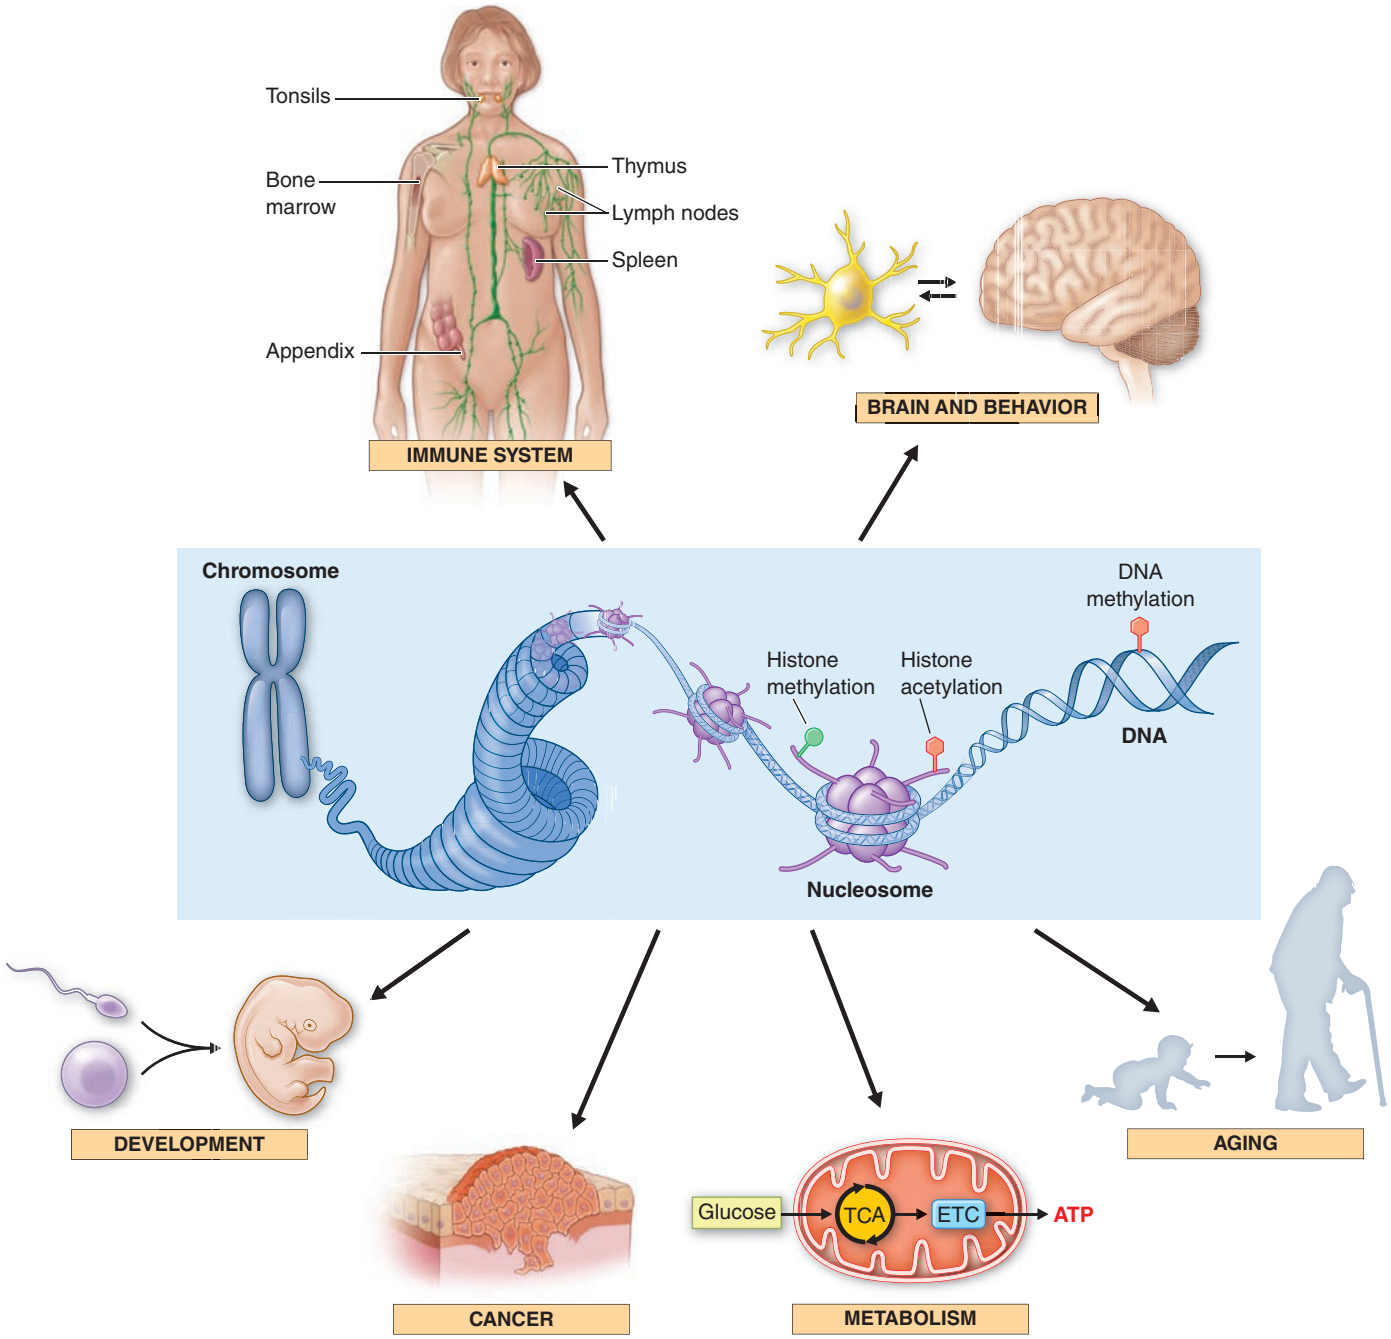

FIGURE 483-1 Epigenetic pathways influence multiple physiologic and disease pathways. As depicted in the center of the illustration, epigenetics refers to the chemical modifications of DNA and histones, which influence chromatin structure, gene expression, and susceptibility to mutations. These molecular pathways, in turn, play important roles in development, cancer, metabolism, aging, neural function, and behavior, and in the immune system. ETC, electron transport chain; TCA, tricarboxylic acid.

methylation state after DNA replication and after transcription during the S phase of the cell cycle. To further alter and to remove methylation, the TET enzymes (TET1–3) progressively oxidize 5-methylcytosine (5-mC) to 5-hydroxymethylcytosine (5-hmC), to 5-formylcytosine (5-fC), and to 5-carboxylcytosine (5-caC), which are unable to be recognized by DNMT1 but can be removed by additional enzymes. Hence, these are mechanisms to passively lose 5-mC following DNA replication or to actively remove 5-mC, both potentially returning to unmethylated cytosine.

Histone posttranslational modifications (hPTMs) are rich sources of diverse signaling to, and marking of, the chromatin template, including at least 60 different covalent chemical modifications on the histone N- and C-terminal tails and within the globular domains. The hPTMs are added (written) and removed (erased) by enzymes and also serve as sequence- and PTM-specific binding surfaces for effector proteins and complexes (readers) to carry out a wide range of downstream actions including transcription, replication, DNA repair, and recombination. One key point is that the staggering numbers of writers, erasers, and readers provide unlimited potential for diagnostic and therapeutic pharmacologic discovery.

Throughout this chapter, we focus on histone acetylation and methylation, the most abundant and the most well-studied hPTMs (Fig. 483-1), although a wealth of additional modifications, such as serine/threonine/tyrosine phosphorylation, lysine ubiquitination, lysine SUMOylation, and lysine ADP-ribosylation, among others, play important roles in transcriptional and chromatin regulation. For instance, histone phosphorylation targets histone H2A at Ser139 (γH2A.X), which marks DNA double-strand breaks immediately following DNA damage and is critical for the recruitment of the DNA repair machinery. Histone mono-ubiquitination functions similarly to other hPTMs, in signaling and marking the chromatin template, in particular serving to mark the initiation region or elongation of

transcribed genes for future rounds of transcription, whereas histone SUMOylation plays a role in transcriptional repression. Polyubiquitination serves to tag proteins for degradation by the proteasome, and dysfunction in this system may play a role in the pathogenesis of neurodegenerative diseases, including Alzheimer's, Parkinson's, and Huntington's. ADP-ribosylation involves a class of enzymes, the poly-ADP-ribose polymerases (PARPs), which transfer ADP-ribose units from NAD^+ to a variety of nuclear proteins. This PARylation alters the chromatin environment through the recruitment and modification of chromatin-associated proteins. In general, future studies of the profuse types and functions of hPTMs will enhance our understanding of these chromatin-based mechanisms and processes and will illuminate new opportunities and targets for therapies.

In contrast, there is extensive understanding of histone lysine acetyltransferases (KATs) and methyltransferases (KMTs). KATs, previously known as HATs, were among the first identified histone modification enzymes. They attach acetyl groups on the lysine residues of histone tails and other proteins, resulting in both a novel side chain (acetyl-lysine) and an increase in negative charge (from positive charged lysine to neutral acetyl-lysine). This alteration results in loosening of chromatin structure to become more permissive to the binding of transcription factors, and acetylation also creates a novel binding surface for the association of reader proteins. Acetylation on core histones, such as lysine 9 on histone H3 (H3K9ac) or lysine 27 (H3K27ac), is typically associated with transcriptional activation. Acetylation is very dynamic and can be rapidly removed by histone deacetylases (HDACs), of which there are multiple classes, including HDACs and sirtuins (NAD-dependent deacetylases), acting to return the lysine to unmodified ground state.

Methylation of histone tails by KMTs provides more nuanced regulation, in that particular methylated lysines are associated with transcriptional activation (e.g., H3K4me3, H3K36me3, H3K79me3), transcriptional repression (e.g., H3K27me3), or DNA repeat and centromeric silencing (e.g., H3K9me3). The output is strictly determined by effector protein binding, as methylation of lysine does not alter side chain electrostatic charge. Lysine methylation is also a more stable chemical modification than is acetylation and turns over more slowly. Lysine demethylases have been identified for several of the specific methylated sites (H3K4, H3K9, H3K36, H3K27, H3K79).

In addition to their impacts upon local chromatin structure through electrostatic alterations and through recruitment of reader effector proteins, some histone modifications can influence other epigenetic processes. For example, H3K36me3 is involved in a variety of transcriptional processes including elongation and splicing. However, through its recruitment and interaction with other methyltransferases, such as DNMT3B and METTL14, H3K36me3 impacts both DNA and RNA methylation, respectively.

Frequently coordinating with histone modification enzymes are nucleosome remodeling enzymes, which use the energy derived from the hydrolysis of ATP to reposition and remove nucleosomes along the DNA template and to exchange core histones and variant histones (including variants that are located at the transcriptional initiation sites [H2AZ] and over the transcribed genes [H3.3]). The nucleosome remodeling complexes can activate or repress transcription. The SWI/SNF family creates nucleosome-free regions for transcriptional activation, the ISWI family evenly spaces nucleosomes to repress transcription, and the INO80 family exchanges H2A with H2AZ at transcription start sites to poise transcriptional activation. Other remodeling complexes play key roles in the DNA damage response and apoptosis, among additional genomic processes.

As alluded to above, RNA can also be methylated, and "RNA epigenetics" is now an emerging area of gene regulation beyond the direct methylation of DNA and hPTMs. Methylation of RNA, such as messenger RNAs (mRNAs), has been known to exist for over half a century. However, in the last decade, the discovery of enzymes that perform reversible methylation of RNAs led to an explosion of this new field, called *epitranscriptomics*. Indeed, RNA methylation leads to mRNA degradation or facilitates translation. However, mRNA methylation itself occurs co-transcriptionally. Notably, the writer methyltransferase enzymes (METTL3, METTL14) and the demethylases (ALKBH5, FTO) have important roles in a variety of disease pathologies.

Because multiple enzymes redundantly and synergistically write, erase, and recognize these modifications on DNA, RNA, and histones, there is great complexity and the potential for fine-tuning of gene regulation. While extensive knowledge gaps remain to fully explicate these mechanisms of gene regulation, epigenetics has become a fully established discipline within biomedical research. In the coming years, it is likely that the basic understanding of these processes will be further harnessed for further betterment of human health.

EPIGENETICS IN DEVELOPMENT AND DIFFERENTIATION

Epigenetic processes are critical to organismal development and to cellular differentiation and reprogramming of cell fate (Fig. 483-1). Transcription factors establish the epigenomic landscape that enables and stabilizes cell-type-specific gene expression while simultaneously ensuring stable repression of alternative cell fates. This results in chromatin profiles that display remarkable cell-type specificity in differentiated cells, particularly at the key regulatory nodes of gene enhancers, which are gene-distal DNA elements that control transcription. In fact, epigenome profiling of the chromatin landscape in tumors of unknown cell origin can provide a better index of the origin tissue than does DNA sequencing of gene mutations within the tumor.

The cell-type-specific epigenetic program is first derived from the template of embryonic stem cells, where numerous genes required for differentiation exist in a "bivalent" state, marked by both the activating histone modification, H3K4me3, and the repressive modification, H3K27me3. Due to this unstable epigenetic state, the genes are "poised" for activation or for repression, depending on their subsequent cell fate. Critical genes directing toward a specific cell fate will be turned on, with maintained H3K4me3 and erased H3K27me3, whereas genes leading toward alternative fates will be repressed, with maintained H3K27me3 and removed H3K4me3. Once differentiated, an epigenetic barrier will prevent the cells from returning to the stem cell state. For example, constitutive heterochromatin in the form of H3K9me3 can serve as a barrier to cellular reprogramming when attempting to create induced pluripotent stem cells, and inhibiting the enzymes that catalyze H3K9me3, such as SUV39H1, can enhance reprogramming efficiency.

DNA methylation contributes to the specification of cell fate and to other developmental pathways. DNA methylation alterations are involved in critical processes ranging from sex chromosome dosage compensation to coordinating expression of imprinted genes. Disruption of this latter process can lead to imprinting disorders including Prader-Willi syndrome, Angelman syndrome, and Beckwith-Wiedemann syndrome.

Beyond embryonic development, epigenetics can provide the necessary coordination and balance between adult stem cell self-renewal compared to cell differentiation. This epigenetic control is critical, as impaired self-renewal can lead to stem cell exhaustion and premature aging, while excessive self-renewal may promote cancer. Key epigenetic regulators tend to play conserved roles across diverse tissue types. For instance, BMI1, a component of the polycomb repressive complex 1 (PRC1), is required for stem cell proliferation and self-renewal, and its ablation leads to stem cell depletion in hematopoietic, epidermal, muscle, intestinal, and mammary stem cells. Similarly, the DNA methyltransferase DNMT1 is required for stem cell self-renewal in hematopoietic, epidermal, and mammary stem cells. HDACs 1 and 2 possess some overlapping functions and are required for normal epidermal differentiation. Likewise, a loss of these HDAC enzymes in hematopoietic stem cells can lead to failure of differentiation and severe anemia. These factors represent repressive chromatin regulation, leading to the general concept that restraining specific transcription pathways related to differentiation are crucial to maintaining undifferentiated self-renewing stem cell pools.

The epigenetic regulation of the tumor suppressor p16 (*CDKN2A*) locus during differentiation provides a prime example of this finely tuned system. For example, as mentioned above, DNMT1 is necessary

for self-renewal in human epidermal stem cells. Levels of DNMT1 are high in the basal undifferentiated layer of the epidermis, decreasing progressively with epidermal stratification, leading to de-repression of the tumor suppressors p16 and p15, thereby promoting cell cycle arrest and full differentiation. BMI1 displays a similar phenotype in both hematopoietic and epidermal stem cells, repressing key genes that promote differentiation, such as *p16* and *p19ARF*. Consistently, a loss of BMI1 leads to premature differentiation and defective self-renewal. In addition to the repression provided by DNMT1 and BMI1, the p16 locus is highly decorated with the repressive H3K27me3 catalyzed by EZH2 in epidermal stem cells. Then, during epidermal differentiation, H3K27me3 is removed by the KDM6B (JMJD3) histone demethylase. Loss of this control over programmed p16 expression occurs in epithelial cancers, such as squamous cell carcinoma (SCC), where EZH2 is overexpressed and KDM6B expression is lost. Breast cancer is another example where progesterone can increase levels of EZH2 to promote mammary epithelial cell proliferation, and excessive EZH2 expression can occur in cancer. This exemplifies how epigenetics can integrate environmental signals and have a profound influence on the fine balance between stem cell maintenance and overt carcinogenesis. In general, a recurrent theme in cancer is loss of key chromatin regulation that promotes cell differentiation, combined with gain of activities that promote stemness.

Chromatin-modifying enzymes also play a major role in influencing cell-type specificity. High levels of EZH2 that modify H3K27me3 promote adipogenesis while simultaneously inhibiting osteogenesis. In contrast, the H3K27me3 demethylases, KDM6A (UTX) and KDM6B, derepress those same genes, driving stem cells toward osteogenesis. Through interactions with tissue-specific master regulators, epigenetic modifiers also shape cell-type specificity. In the epidermis, p63, the p53 family member that is a master regulator of the epidermal compartment, interacts with several chromatin regulators including HDAC1 and HDAC2, SATB1, MLL4 (KMT2D), and BRG1 to orchestrate epidermal differentiation. Similarly, the gene-activating H3K4 histone methyltransferases, MLL3 (KMT2C) and MLL4, are required for adipogenesis by forming a complex with the transcriptional activator ASC2 and the transcription factor PPARγ to induce adipogenic genes. Overall, loss of epigenetic regulation can reduce cell differentiation and increase stem cell specification to drive diseases encompassing development, cancer, and, broadly, diseases associated with aging.

EPIGENETICS OF METABOLISM

One of the fascinating aspects of epigenetics is that it represents a mechanism for direct connection between the environment and gene expression. Numerous studies in the field of metabolism have identified a complex interplay between diet, metabolism, and the epigenome (Fig. 483-1). Seminal findings in *Drosophila* and mice have shown that changes in diet, particularly the paternal diet, and other environmental factors, can influence the metabolism of offspring, ultimately promoting obesity in later generations. Epidemiologic studies in humans have supported these results, as the nutritional status of grandparents has been correlated with phenotypic effects in grandchildren. In fact, diet can directly affect the levels and activity of chromatin modifiers.

For instance, high-fat diets reduce histone acetylation through their ability to inhibit the enzymes ACLY and ACSS2, which produce acetyl-CoA. Levels of acetyl-CoA, in comparison to all measured metabolites, are indeed the best predictor of histone acetylation levels. Consistent with this, increased acetyl-CoA correlates with rising levels of total histone acetylation, including at the promoters of growth-associated genes. This increase in nuclear acetylation is associated with cell cycle progression and proliferation, and it can have clinically relevant downstream effects. For example, high levels of acetyl-CoA can delay stem cell differentiation and suppress autophagy. The oncogenes MYC and AKT can both hijack metabolic networks to enhance nutrient uptake by cancer cells, thus promoting acetyl-CoA production and resulting in both the initiation and progression of tumorigenesis. Recent evidence suggests that dietary intake of alcohol can directly contribute to acetate levels and therefore histone acetylation in the brain, with effects on the transcription of genes involved in learning and memory.

Contrary to convention that metabolic enzymes are strictly mitochondrial or cytosolic, certain metabolic enzymes can be present in the nucleus and can thereby directly regulate histone acetylation enzymes. This is the case for several enzymes that generate acetyl-CoA, including ACLY, PDH, and ACSS2, which generate acetyl-CoA from citrate, pyruvate, and acetate, respectively. Further, ACSS2 can be chromatin-bound to regulate gene expression, leading to physiologic responses such as autophagy in the liver and mammalian hippocampal function in learning. This direct metabolic-epigenetic enzyme cross-talk illuminates a crucial local role of the acetyl-CoA metabolite to effect rapid gene transcription and represents a fertile intersection for future therapeutics.

Methylation is also altered by metabolism. S-adenosylmethionine (SAM) is the key metabolic co-factor for histone and DNA methylation. Dietary factors are estimated to explain 30% of the variation in human serum methionine concentration and hence can alter SAM levels and histone methylation. For example, dietary methionine availability and intracellular production of SAM affect the levels of histone H3K4me3 associated with transcriptional activation. Furthermore, these fluctuations can have critical physiologic consequences: DNA methylation levels in rectal mucosa and colonic polyps are increased by higher levels of dietary folate, and a diet low in methyl donors reduces the formation of gastrointestinal cancers in mice predisposed to these tumors. Methionine metabolism and the availability of SAM regulates stem cell differentiation and contributes to carcinogenesis. For instance, cancers with mutations in metabolic regulatory genes such as *IDH1/2*, *FH*, and *SDH* lead to the accumulation of by-products (2-hydroxyglutarate, fumarate, and succinate, respectively), which all inhibit α-ketoglutarate (α-KG)–dependent histone demethylases and thus promote hypermethylation and lead to impaired cellular differentiation. Notably, some of the α-KG–dependent demethylases, which are highly mutated in numerous cancers (i.e., KDM5A, KDM6A), also serve as cellular oxygen sensors, thus linking environmental oxygen levels to epigenetic control of methylation levels. In contrast to hypermethylated states, loss of the *MTAP* gene, which is part of the 9p21 locus containing p16 and one of the most frequent events in human cancer, disrupts normal methionine metabolism. This both lowers methylation levels, and, interestingly, also sensitizes cancer cells to inhibitors of the PRMT5 methyltransferase, therefore opening a new therapeutic opportunity. These observations illustrate how connections between epigenetics and metabolism can generate unanticipated advances in medicine. Furthermore, these data highlight the tight interconnections between environmental inputs, metabolism, and epigenetics.

CANCER EPIGENETICS

Cancer is now understood to be a mixed genetic and epigenetic disease, as epigenetic dysregulation is pervasive in human cancers (Fig. 483-1). Beyond simple activation of oncogenes or reduced expression of tumor suppressors, epigenetic mechanisms can contribute to chemotherapy resistance and to failure of antitumor immunity. Accordingly, the development of drugs targeting epigenetic pathways is one of the most active areas of clinical and pharmaceutical development, with several compounds already approved for human use and shown to be effective in a variety of cancers. Epigenetic perturbations in cancer largely affect chromatin-regulating enzymes, which represent robust targets for development of novel small-molecule inhibitors, especially as compared with canonical oncogenic transcription factors (e.g., MYC) and tumor suppressors (e.g., p53).

Epigenetics can contribute to carcinogenesis in a variety of ways. First, on a global scale, chromatin organization is the single most influential factor in determining local mutation rate across the genome. Analysis of abundant tumor sequencing data has demonstrated that heterochromatic regions of the genome contain a higher frequency of mutations compared with more open euchromatic regions. This difference is due to the improved accessibility of the DNA repair machinery to less compact, more open regions of chromatin.

The first discovery of an epigenetic mutation was found in 1998 when the chromatin remodeler *SMARCB1* was shown to drive the formation of malignant rhabdoid tumors. Extensive sequencing of human

tumors from the majority of cancer types has been performed by The Cancer Genome Atlas (TCGA) consortium, and remarkably, 25–30% of identified cancer driver mutations occur in chromatin regulatory proteins. Similar to *SMARCB1*, numerous other chromatin modifiers (e.g., methyltransferases *MLL3* and *MLL4*, and acetyltransferases *EP300* and *CBP*) and nucleosome remodeling enzymes and associated complex components (e.g., *SMARCA4*, *SMARCA2*, *ARID1A*) are heavily mutated and inactivated in many cancers. The majority of these mutations are loss-of-function mutations, and indeed, enzymes like MLL4 and demethylase KDM6A possess tumor-suppressive activity. In contrast, the H3K27me3 histone methyltransferase *EZH2* is an oncogene, and accordingly, it is overexpressed in many advanced-stage or metastatic solid tumors such as breast cancer, prostate cancer, and melanoma. Mechanistically, EZH2 represses the *p16* tumor suppressor and other cell cycle genes required for cell cycle exit via H3K27me3 deposition. Consistent with a broad growth regulatory role, EZH2 inhibitors are therapeutically successful for a number of cancers in preclinical models and are being actively studied for B-cell lymphoma, melanoma, and other solid tumors.

Recently, provocative evidence has emerged for a direct tumorigenic role of histones based on the discovery of causative mutations, such as histone H3 mutations identified in pediatric high-grade gliomas. Specifically, the majority of these mutations are in the H3 variant H3.3, where lysine 27 is replaced by methionine (K27M). Similarly, >90% of chondroblastomas replace lysine 36 with methionine (K36M) in histone H3.3. These effects appear to be dominant negative because (1) in H3.3 these are heterozygous mutations, and (2) the mutations also occur in the canonical H3, which exists in ~30 orthologous genes in the human genome. Thus, a minority of H3/H3.3 mutant protein leads to global defects in the associated histone modifications (K27 or K36 methylation), possibly via irreversible inhibition of the cognate enzymes by the mutant histones. These "oncohistone" mutations promote resistance to apoptosis and failure of normal differentiation in a number of pediatric and adult cancers.

Beyond mutations, genetic translocations involving chromatin modifiers also implicate chromatin pathways as direct drivers in cancer. MLL1 (KMT2A), the H3K4 histone methyltransferase, is a frequent translocation partner occurring in adult and pediatric acute myeloid leukemia (AML) and in ~80% of infant acute lymphoid leukemia (ALL) cases. MLL1 can fuse with >70 translocation partners, and these mutant proteins prevent normal hematopoietic differentiation. Consistent with a causative role of MLL1 in these gene fusions, drugs inhibiting the catalytic activity of MLL1 are effective in preclinical models of AML and are currently being evaluated in human clinical trials.

Given the abundance of epigenetic abnormalities in cancer combined with the inherent reversibility of epigenetic changes, extensive efforts are underway to develop epigenetic drugs. The first epigenetic therapeutic involved the use of DNA methylation inhibitors (DNMTi) to reactivate tumor-suppressor genes. Interestingly, the mechanism of traditional chemotherapeutics, such as azacitidine and decitabine, is to inhibit DNMT1, thereby promoting global hypomethylation; these are currently in clinical use for myelodysplastic syndrome (MDS) and AML. In a second broad mechanism, loss of acetylation occurs in many cancers, and thus, HDAC inhibitors (HDACi) are under intensive development. HDACi are effective and approved for treatment in cutaneous T-cell lymphoma and multiple myeloma. Bromodomain (BRD)-containing proteins bind to lysine acetylated target proteins, including histones, and rationally designed BET inhibitors (BETi) block their binding. BETi reduce the amplified expression of oncogenes such as *MYC* in hematologic cancers. Current studies are now focused on optimizing combinatorial epigenetic therapies with conventional chemotherapies and immunotherapies, particularly given the ability of epigenetic therapeutics to promote reexpression of tumor antigens and interferon (IFN)-mediated antitumor immunity. Indeed, the development of a new generation of more specific epigenome-targeted inhibitors, combined with our increased knowledge of the underlying epigenetic mechanisms contributing to tumorigenesis, has enabled a precision medicine–based approach to harnessing the potential of these drugs. This may be particularly valuable in the context of improving patient responses to a variety of therapies beyond chemotherapies and immunotherapies, such as radiation and hormone therapies.

There are several hundred chromatin enzymes and binding proteins in the human genome, and the current focus is to identify more specific inhibitors. Indeed, targeted inhibitors of numerous mutated chromatin regulators have been developed, with >30 compounds currently in various stages of development and preclinical trials. Some notable examples showing early clinical success include EZH2 inhibitors for lymphomas, sarcomas, and melanoma, IDH inhibitors for AML and gliomas carrying mutant *IDH1* or *IDH2* genes, LSD1 inhibitors for AML and small-cell lung cancer, and DOT1L and MLL1 inhibitors for leukemias with activated MLL1. Given the broad potential effects of epigenetic regulators, it is perhaps not surprising that there have been some dose-limiting toxicities, particularly among those that are less target-specific. Collectively, the emerging picture is that the most effective and robust use of epigenetic drugs in cancer will be fine-tuning and potentiating the effects of other therapies that are either incompletely effective or marked by widespread resistance.

EPIGENETICS OF AGING

Like many diseases of aging, human aging itself results from the complex interplay between genes and the environment. Evidence that the epigenome may be the key link between these processes derives from observations that numerous environmental stimuli and stressors—ranging from diet and exercise to hormones and circadian rhythms—contribute to both aging and epigenetic alterations (Fig. 483-1). Thus, a lifetime of exposures progressively disrupts the chromatin landscape. These age-dependent changes in chromatin organization increase the susceptibility of the genome to mutations and also reduce transcriptional fidelity. Further, provocative findings in model systems demonstrate that stress-induced epigenetic changes can be transmitted over several generations and can even affect the life span of later generations. Among these global epigenetic alterations, there is dysregulation of histone modifications and a general loss of histone proteins with aging across taxa. Amazingly, experimental increases in histone levels, particularly histones H3 and H4, but not H2A or H2B, can reverse these age-related changes in mammalian cells and in the yeast *Saccharomyces cerevisiae* model.

Thus, the sum of current evidence suggests a model of aging via a general increase in activating epigenetic modifications along with a loss of repressive modifications. Together these changes create a state of transcriptional instability and "noise" that inhibits accurate transcription. Cells from patients with Hutchinson-Gilford progeria syndrome (HGPS), the most severe form of human premature aging, display reduced levels of both H3K9me3 and H3K27me3 repressive chromatin. In another premature aging disease, Werner syndrome, DNA damage induces global loss of H3K9me3 and H3K27me3 due to the inherent absence of the Werner syndrome ATP-dependent DNA helicase, which is critical for DNA repair. Such heterochromatin loss is not limited to premature aging conditions, as aged cells derived from healthy older humans display age-dependent loss of H3K9me3 leading to aberrant expression of normally repressed transposable elements. Activation of these mobile elements correlates with neurodegenerative disorders and may also promote other aging-related phenotypes such as cancer. Human fibroblasts undergoing cellular senescence (exit from cell cycle due to replicative or other stress) undergo destabilization of compact heterochromatin adjacent to the nuclear periphery, in so-called lamin-associated domains (LADs). At LADs, in addition to a reduction of repressive histone modifications as discussed above, there are broad new regions of the euchromatic histone modification H3K4me3. This general loss of heterochromatin can promote the activation of cytosolic DNA and RNA sensing pathways that promote innate immune signaling and "inflammaging."

In addition to age-associated alterations of histone modifications, direct manipulation of chromatin-modifying enzymes that control these marks affects the balance between heterochromatic and euchromatic regions, and it alters the life span of model organisms. Inhibiting the H3K27me3 histone demethylase KDM6A results in increased repressive H3K27me3 and extended life span in *Caenorhabditis elegans*.

Consistent with this, genetic reduction of enzymes (*ash-2*, *set-2*, *wdr-5*) that add the activating H3K4me3 histone modification also extends life span in *C. elegans*. The consequences of these genetic manipulations nicely correspond to the observed changes in histone modifications as described above. Beyond histone-modifying enzymes, dysregulation of the levels or function of chromatin remodelers can also affect life span in model organisms. This dysregulation occurs in humans as well, as in the nucleosome remodeling deacetylase complex (NuRD), which is reduced in HGPS fibroblasts and in aged healthy donors.

In addition to age-related changes in histone methylation, histone acetylation also contributes to aging phenotypes. Dysregulation of histone acetyltransferases (HATs) and HDACs is associated with reduced longevity across model organisms. Further, sirtuin deacetylases (class III NAD^+-dependent HDACs) promote health span and life span across species as key mediators of pro-longevity effects of caloric restriction. Indeed, loss of Sirt6 results in premature aging in mice, while caloric restriction–induced increases of Sirt1 and Sirt6 expression can delay aging. As discussed previously, metabolism and acetylation are intricately linked, and the sirtuins, via NAD^+ levels, and other HDACs may play key roles connecting the environment, gene expression, and physiologic output. For instance, exercise in humans reduces activity of HDACs 4 and 5, leading to increased H3K36ac in skeletal muscle, which likely promotes beneficial gene expression.

Epigenetic alterations with aging are not limited to histone modifications and extend to DNA methylation. Consistent with the histone patterns, DNA methylation data support the model described above—that is, general decompaction of the epigenome with aging. Specifically, levels of 5-methylcytosine (5-mC) are reduced in senescent human cells, and global DNA hypomethylation occurs across the human genome with aging. Concurrent with this overall hypomethylated state, there are local regions of hypermethylation focused near CpGs at gene promoters, particularly at genes that maintain cellular differentiation and cell identity. This epigenetic disruption during aging thus leads to profound changes in transcription. For example, in hematopoietic stem cells, DNA hypermethylation blocks proper binding of transcription factors, resulting in dysregulation of normal gene expression with aging. Importantly, these patterns are not merely stochastic alterations in response to environmental stressors throughout aging. Indeed, the methylation status of a defined number of CpG sites is a highly accurate predictor of chronologic age in human tissues. This work reveals that DNA methylation status with aging outperforms previous standard biomarkers of aging, such as p16 expression levels and telomere length, and will be highly valuable in the near future to gauge effects of treatment aiming to ameliorate diseases of aging.

EPIGENETICS OF THE BRAIN AND BEHAVIOR

Brain disorders are among the greatest clinical challenges to understand and to treat. Most neurologic and psychiatric disorders result from complex dysregulation of numerous genes and pathways. In this interplay between underlying genetic predisposition and external environmental factors, aberrant epigenetic regulation is increasingly recognized as a potentially key modulator (Fig. 483-1).

More directly, however, several progressive neurodevelopmental disorders are caused by germline mutations in chromatin regulators. Mutations in methyl CpG binding protein 2 (*MECP2*), a protein important for binding to methylated DNA and contributing to gene repression, are the major cause of Rett syndrome. MeCP2 loss leads to overactive gene transcription in neurons and impaired presynaptic excitatory functions. Similarly, Kabuki syndrome, another progressive neurodevelopmental disorder, is caused by germline mutations in either the H3K4me1 histone methyltransferase, *MLL4* (*KMT2D*), or the H3K27me3 demethylase, *UTX* (*KDM6A*). This disorder may derive from dysregulation of transcriptional enhancers, a major class of gene regulatory elements, as both *MLL4* and *UTX* play a key role in activation of enhancers. Finally, the acetyltransferase CBP (*CREBBP*) also is important for gene enhancer function and, when mutated, can lead to Rubinstein-Taybi syndrome, a cause of intellectual disability.

Beyond germline mutations, altered methylation dynamics can drive disorders of neural development and of neurodegeneration. Fragile X syndrome, characterized by learning disabilities and cognitive impairment, is caused by mutations in the *FMR1* or *FMR2* gene or by hypermethylation of the transcriptional promoters regulating *FMR1* or *FMR2*. Similarly, Prader-Willi syndrome and Angelman syndrome, neurodevelopmental conditions caused by abnormal imprinting of the paternal or maternal chromosomal region (15q11-13), respectively, are frequently caused by aberrant DNA methylation. Further, DNA hypomethylation is implicated in some neurodegenerative conditions. For instance, in Parkinson's disease, several genes involved in pathogenesis are hypomethylated due to DNMT1 depletion, including the α-synuclein gene (*SCNA*). In Alzheimer's disease (AD), DNA hypomethylation occurs at promoters of key pathogenic genes such as amyloid precursor protein (*APP*). Indeed, APP promoter methylation is responsive to environmental factors, including aging, a major risk factor for AD. Likewise, presenilin-1 (*PSEN1*) is implicated in AD and displays altered DNA methylation in response to variations in metabolic stimuli. Recent evidence from human AD brains demonstrated significant enrichment of H3K9 and H3K27 acetylation and provided evidence that this dysregulation of the epigenome promotes gene transcription pathways involved in AD pathogenesis. Studies of Huntington's disease (HD) have demonstrated DNA hypomethylation and decreased histone acetylation, in part due to altered function of the acetyl transferase CBP, leading to transcriptional dysregulation. Together, these observations underscore altered epigenetic regulation as a crucial feature of neurodegeneration.

Additional gene regulatory proteins in the nervous system interact with and are regulated by chromatin modifiers. REST (repressor element 1–silencing transcription factor) is important in neuronal homeostasis through its ability to recruit chromatin regulatory enzymes, such as histone deacetylases and histone methyltransferases, and via its control over gene expression. REST levels increase with aging and serve a protective function in neurons against age-associated stressors and loss of cognitive function associated with AD. Similar to REST, brain-derived neurotrophic factor (BDNF), another important mediator of neural development and homeostasis, is implicated in a variety of neurologic and psychiatric disorders including HD, depression, schizophrenia, bipolar disorder, and autism. Knockdown of BDNF in the dentate gyrus leads to depression-like behavior in mouse models, and BDNF mediates effects of antidepressant therapies. Chromatin pathways, including DNA methylation/MeCP2 and H3K27me3, play a key role in BDNF regulation as observed in brains from patients with schizophrenia.

Finally, addiction medicine is another frontier where epigenetics holds great promise to reveal connections between environmental exposure and phenotypes. Although still in its early stages in terms of mechanistic understanding, emerging evidence demonstrates disruption of epigenetic homeostasis as a consequence of addictive substances ranging from alcohol to cocaine. For example, the acetylation of regulatory elements in the *FOSB* gene by the histone acetyltransferase CBP is associated with behavioral effects of cocaine. Opioid exposure appears to promote a generally more open and permissive state of chromatin marked by increases in histone acetylation and reductions in histone methylation, which may allow for a more hyperresponsive state and reinforce reward-seeking behaviors. Ethanol also induces histone acetylation and a decompacted chromatin structure with direct effects on learning and memory function.

EPIGENETIC INFLUENCES ON INFECTION, IMMUNITY, AND INFLAMMATION

Alterations in gene expression patterns are important determinants of immune-mediated disease, and in turn, epigenetics regulates infection, immunity, and inflammation (Fig. 483-1). Treatment with immune-stimulating agents such as lipopolysaccharide (LPS) and tumor necrosis factor α activate expression of numerous inflammatory genes within hours, with precise gene pathways and activation kinetics determined by the cellular epigenetic state. HATs and HDACs are critical components of this response, coordinating with proinflammatory transcription factors such as AP-1 and NF-κB, to activate (HATs) and to repress (HDACs). For example, corticosteroids recruit HDAC2 to promoters

of NF-κB-stimulated inflammatory genes to prevent activation during asthma treatment.

Type 1 IFN responses are exceptional examples of regulatory complexity governed by epigenetic control. In an unstimulated state, the H3K9 methyltransferases G9a (*EHMT2*) and EHMT1 suppress expression of IFN and IFN-induced genes. Upon induction of IFN-stimulated genes, STAT transcription factors recruit chromatin remodeling complexes, such as BAF (*SMARCA4*), and recruit HATs including p300, CBP, and GCN5 (*KAT2A*). In turn, chromatin remodeling and acetylation recruit chromatin binding proteins including the bromodomain protein, BRD4, which promotes transcriptional elongation and full activation. Beyond the DNA level, METTL3-mediated m^6A methylation on mRNAs also is a critical regulator of IFN signaling in a variety of distinct cellular contexts.

Major regulators of adaptive immunity pathways are similarly epigenetically regulated. CD4+ and CD8+ T cells undergo extensive changes in histone modification profiles during differentiation to distinct subsets of effector T cells. For example, genes associated with effector T-cell functions in CD8+ memory T cells (such as *PRDM1*, *KLRG1*, *IFNG*) display enrichment of H3K4me3 and low levels of H3K27me3 compared with those genes in naïve T cells. DNA methylation also plays an important regulatory role and may contribute to disease. For example, CD4+ T cells from individuals with rheumatoid arthritis (RA), systemic scleroderma, and latent autoimmune diabetes in adults display hypermethylation of the *FOXP3* gene, which activates regulatory T cells that dampen immune responses. In addition, hypermethylation of the *CTLA4* locus occurs in regulatory T cells from RA patients, impairing their immunosuppressive abilities.

During infection, epigenetic processes can play critical roles in both the immune response and defense against pathogens, as well strategies exploited by microorganisms to co-opt the host cellular machinery to advantage of the pathogen. Respiratory syncytial virus (RSV) infection promotes the expression of the histone demethylase KDM5B, which removes H3K4 methyl groups from antiviral genes such as type I IFNs, driving a switch from T helper 1 to T helper 2–type immune responses, thereby contributing to chronic infection. Similarly, influenza upregulates the repressive H3K9me3 methyltransferase SETDB2 to block expression of CXCL1 and a variety of NF-κB target genes involved in attracting neutrophils and host defense, both serving to lengthen the infection and contributing to bacterial superinfection. Regarding the host response to infection, studies have revealed that differences in host tissue-, age-, and sex-biased epigenetic profiles might shape susceptibility and responses to infection. For example, differential DNA methylation at the *ACE2* gene may impact expression levels of this key cellular receptor and ultimately the ability of SARS-CoV-2 to infect hosts, while alterations in antiviral IFN signaling may lead to more severe COVID-19 infection and disease.

Although mechanistic studies remain limited, there are numerous examples of epigenetic-based therapies associated with extensive effects on the immune system, underscoring the potential hope for eventual treatment of immune-related conditions. For example, the DNA methylation inhibitors azacitidine and decitabine have immunosuppressive effects possibly mediated by enhanced expression of *FOXP3*, which generally suppresses immune responses. HDAC inhibitors upregulate and downregulate immune genes, and they inhibit cytokine production in macrophages from patients with RA. Further, the HDAC inhibitors vorinostat and panobinostat inhibit primary B-cell responses and antibody production in vitro and in vivo. Given these broad effects, it is not surprising that the HDAC inhibitor trichostatin A (TSA) has efficacy in various model systems for treatment of RA, systemic lupus erythematosus (SLE), asthma, acute kidney injury, sepsis-induced lung and cardiac damage, and acute pancreatitis. Similarly, BETi also display broad effects in blocking antigen presentation and T- and B-cell activation and thus beneficial protective effects in a variety of inflammatory settings including autoimmunity, sepsis, atherosclerosis, psoriasis, periodontitis, and arthritis. Beyond these "broad-spectrum" epigenetic inhibitors, GSK-J4, which is a specific inhibitor of the H3K27me3 demethylases KDM6A and KDM6B, has anti-inflammatory activity, presumably by preventing loss of H3K27me3 repression over inflammatory genes. Similarly, inhibition of the H3K4me3 histone methyltransferase, MLL1 blocks the induction of proinflammatory cytokine gene expression in a variety of contexts.

CONCLUSIONS

Due to the enormity and complexity of the chromatin and epigenetics fields and their reach into all areas of biology and medicine, it is not possible to cover such a broad scope in a single chapter. Thus, here we provide a concise snapshot highlighting key areas of development in medicine. We hope to have conveyed the tremendous excitement and promise that pervades the discipline. Indeed, given the exponential growth in uncovering the interface between the epigenome and epigenetic therapies with the environment and disease, there is little doubt that the coming years will bring important additions to this field.

484 Applications of Stem Cell Biology in Clinical Medicine

John A. Kessler

Damage to an organ initiates a series of events that lead to the reconstruction of the damaged tissue, including proliferation, differentiation, and migration of various cell types; release of cytokines and chemokines; and remodeling of the extracellular matrix. Endogenous stem and progenitor cells are among the cell populations that are involved in these injury responses. In normal steady-state conditions, an equilibrium is maintained in which endogenous stem cells intrinsic to the tissue replenish dying cells. After tissue injury, stem cells in organs such as the liver and skin have a remarkable ability to regenerate the organ, whereas other stem cell populations, such as those in the heart and brain, have a much more limited capability for self-repair. In rare circumstances, circulating stem cells may contribute to regenerative responses by migrating into a tissue and differentiating into organ-specific cell types. The goal of stem cell therapies is to promote cell replacement in organs that are damaged beyond their ability to self-repair.

GENERAL STRATEGIES FOR STEM CELL REPLACEMENT

At least three different therapeutic concepts for cell replacement can be envisaged **(Fig. 484-1)**. One therapeutic approach involves direct

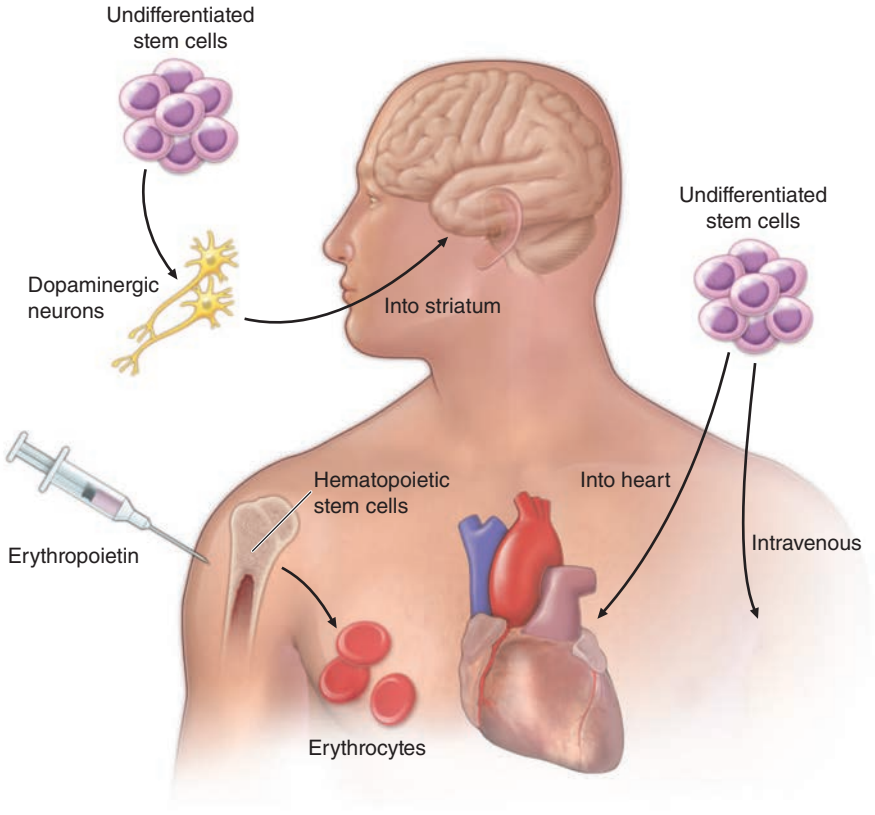

FIGURE 484-1 Strategies for transplantation of stem cells. 1. Undifferentiated or partially differentiated stem cells may be injected directly into the target organ or intravenously. 2. Stem cells may be differentiated ex vivo before injection into the target organ. 3. Growth factors or other drugs may be injected to stimulate endogenous stem cell populations.

administration of stem cells. The cells may be injected directly into the damaged organ, where they can differentiate into the desired cell type. Alternatively, stem cells may be injected systemically since they have the capacity to home in on damaged tissues by following gradients of cytokines and chemokines released by the diseased organ. A second approach involves transplantation of differentiated cells derived from stem cells. For example, pancreatic islet cells can be generated from stem cells before transplantation into diabetic patients, and cardiomyocytes can be generated to treat heart disease. A third approach involves stimulation of endogenous stem cells to facilitate repair. This goal might be accomplished by administration of appropriate growth factors and drugs that amplify the number of endogenous stem/progenitor cells and/or direct them to differentiate into the desired cell types. Therapeutic stimulation of precursor cells is already a clinical reality in the hematopoietic system, where factors such as erythropoietin, granulocyte colony-stimulating factor, and granulocyte-macrophage colony-stimulating factor are used to increase production of specific blood elements. In addition to these strategies for cell replacement, a number of other approaches could involve stem cells for ex vivo or in situ generation of tissues, a process termed *tissue engineering*. Stem cells are excellent candidates as vehicles for cellular gene therapy **(Chap. 470)**, and they also potentially can be used to modify immune responses. For example, genetically modified T cells have been used treat various type of malignancies. Administration of components of stem cells, such as exosomes, also may be used to stimulate regenerative responses. Finally, transplanted stem cells may exert paracrine effects to promote repair of damaged tissues without differentiating to replace lost cells.

Stem cell transplantation is not a new concept but rather is already part of established medical practice. Hematopoietic stem cells (HSCs) **(Chap. 96)** are responsible for the long-term repopulation of all blood elements in recipients of bone marrow transplants, and hematopoietic stem cell transplantation is the gold standard against which other stem cell transplantation therapies are measured. Transplantation of differentiated cells is also a clinical reality, and donated organs and tissues are often used to replace damaged tissues. However, the need for transplantable tissues and organs far outweighs the available supply, and organ transplantation has limited potential for some tissues, such as the brain. Stem cells offer the possibility of a renewable source of replacement cells for virtually all organs.

SOURCES OF STEM CELLS FOR TISSUE REPAIR

A variety of different types of stem cells could be used in regenerative strategies, including embryonic stem (ES) cells, induced pluripotent stem (iPS) cells, umbilical-cord blood stem cells (USCs), organ-specific somatic stem cells (e.g., neural stem cells for treatment of the brain), and somatic stem cells that generate cell types specific for the target organ rather than the donor organ (e.g., bone marrow mesenchymal stem cells [MSCs] or CD34+ HSCs for cardiac repair). Although each cell type has potential advantages and disadvantages, there are a number of generic challenges associated with developing any of these cell types into a useful and reliable clinical tool.

Embryonic Stem Cells ES cells have the potential to generate all of the cell types in the body; thus, in theory, there are no restrictions on the organs that could be regenerated. ES cells can self-renew endlessly, so that a single cell line with carefully characterized traits potentially could generate almost limitless numbers of cells. In the absence of moral or ethical constraints (see "Ethical Issues," below), unused human blastocysts from fertility clinics could be used to derive new ES cell lines that are matched immunologically with potential transplant recipients. ES cells also can be derived from unfertilized oocytes by parthenogenesis, but there is debate about whether this alters the ethical issues. However, human ES cells are difficult to culture and grow slowly. Techniques for differentiating them into specific cell types are still nascent. Cells tend to develop abnormal karyotypes and other abnormalities with increased time in culture, and ES cells have the potential to form teratomas if all cells are not committed to the desired cell types before transplantation. Further, human ES cells are ethically controversial, and on these grounds, their use would be unacceptable to some patients and physicians despite their therapeutic potential. Nevertheless, there have been limited clinical trials of ES-derived cells in a number of disorders, including macular degeneration, myopia, heart failure, diabetes, and spinal cord injury (SCI).

Induced Pluripotent Stem Cells The field of stem cell biology was transformed by the discovery that adult somatic cells can be converted ("reprogrammed") into pluripotent cells through the overexpression of four transcription factors normally expressed in pluripotent cells. These iPS cells share most properties with ES cells, although there are distinct differences in gene expression between ES and iPS cells. The initial use of viruses to insert the transcription factors into somatic cells made the resulting cells unsuitable for clinical use. However, a number of strategies have since been developed to circumvent this problem, including the insertion of modified mRNAs, proteins, or microRNAs rather than cDNAs and treatment with small molecules; the use of nonintegrating viruses such as Sendai virus; the insertion of transposons with the programming factors, followed by their subsequent removal; and the use of floxed viral constructs, followed by treatment with Cre recombinase to excise those constructs. iPS cells derived from patients with different disorders are currently being used extensively for disease modeling and drug discovery. However, the safety of iPS cells for use in regenerative strategies in humans remains

to be demonstrated. The first clinical trial in macular degeneration was initially suspended after treatment of one patient because of discovery of a mutation in cells derived for the second patient, but the trial was later resumed and progressed without significant safety issues. In addition to ongoing clinical trials in macular degeneration, trials of iPS cells also have commenced for treatment of heart failure, SCI, and Parkinson's disease, and trials in numerous other disorders are planned. An advantage of iPS cells is that somatic cells from patients would generate pluripotent cells genetically identical to those of the patient, obviating the need for immunosuppression. Further, these cells are not subject to the same ethical constraints as ES cells. It is not clear whether the differences in gene expression between ES and iPS cells will have any impact on their potential clinical utility, and studies of both cell types will be needed to resolve this issue.

Umbilical-Cord Stem Cells USCs are widely available. These cells appear to be associated with less graft-versus-host disease than are some other cell types, such as marrow stem cells. They have less human leukocyte antigen restriction than adult marrow stem cells and are less likely to be contaminated with herpesvirus. However, it is unclear how many different cell types can be generated from USCs, and methods for differentiating these cells into nonhematopoietic phenotypes are largely lacking. Nevertheless, there are ongoing clinical trials of these cells in dozens of disorders, including cirrhosis, cardiomyopathies, multiple sclerosis, burns, stroke, autism, and critical limb ischemia, and cord stem cells have been approved by the Food and Drug Administration for the treatment of certain hematopoietic disorders and cancers.

Organ-Specific Multipotent Stem Cells Organ-specific multipotent stem cells have the advantage of already being somewhat specialized so that the induction of desired cell types may be easier. Cells potentially could be obtained from the patient and amplified in cell culture, circumventing the problems associated with immune rejection. Stem cells are relatively easy to harvest from some tissues, such as bone marrow and blood, but are difficult to harvest from other tissues, such as heart and brain. Moreover, these populations of cells are more limited in potentiality than are pluripotent ES or iPS cells, and they may be difficult to obtain in large quantities from many organs. Therefore, substantial efforts have been devoted to developing techniques for using more easily obtainable stem cell populations, such as bone marrow MSCs, CD34+ HSCs, cardiac mesenchymal cells, and adipose-derived stem cells (ASCs), for use in regenerative strategies. Tissue culture evidence suggests that these stem cell populations may be able to generate differentiated cell types unrelated to their organ source (including myocytes, chondrocytes, tendon cells, osteoblasts, cardiomyocytes, adipocytes, hepatocytes, and possibly neurons) in a process known as *transdifferentiation*. However, it is still unclear whether these stem cells are capable of generating differentiated cell types that integrate into organs, survive, and function after transplantation in vivo. A number of early studies of MSCs transplanted into heart, liver, and other organs suggested that the cells had differentiated into organ-specific cell types with beneficial effects in animal models of disease. Unfortunately, subsequent studies revealed that the stem cells had simply fused with cells resident in the organs and that the observed beneficial effects were due to paracrine release of trophic and anti-inflammatory cytokines. Further studies will be necessary to determine whether transdifferentiation of MSCs, ASCs, or other stem cell populations occurs at a high enough frequency to make these cells useful for stem cell replacement therapy. Despite the remaining issues, a large number of clinical trials of MSCs, autologous HSCs, USCs, and ASCs are being performed in many disorders, including ischemic cardiac disease, cardiomyopathy, diabetes, stroke, cirrhosis, amyotrophic lateral sclerosis (ALS), muscular dystrophy, and other disorders. However, in general, therapeutic benefits to humans have not been as robust as the findings in animal models. Another approach has been to derive organ-specific stem cells by parthenogenesis, and a clinical trial of neural stem cells derived this way has begun for Parkinson's disease.

Regardless of the source of the stem cells used in regenerative strategies, a number of generic problems must be overcome for the development of successful clinical applications. Methods must be devised to reliably generate large numbers of specific cell types, to minimize the risk of tumor formation or proliferation of inappropriate cell types, to ensure the viability and function of the engrafted cells, to overcome immune rejection when autografts are not used, and to facilitate revascularization of regenerated tissue. Each organ system also will pose tissue-specific problems for stem cell therapies.

DISEASE-SPECIFIC APPLICATIONS OF STEM CELLS

Ischemic Heart Disease and Cardiomyocyte Regeneration Because of the high prevalence of ischemic heart disease, extensive efforts have been devoted to the development of strategies for stem cell replacement of cardiomyocytes. Historically, the adult heart has been viewed as a terminally differentiated organ without the capacity for regeneration. However, recent studies have demonstrated that the heart has the capacity for low levels of cardiomyocyte regeneration (Chap. 237). This regeneration appears to be accomplished by cardiac stem cells resident in the heart and possibly also by cells originating in the bone marrow. The heart might be an ideal source of stem cells for therapeutic use, but techniques for isolating, characterizing, and amplifying large numbers of these cells have not yet been perfected. For successful myocardial repair, stem cell therapy must deliver cells either systemically or locally, and the cells must survive, engraft, and differentiate into functional cardiomyocytes that couple mechanically and electrically with the recipient myocardium. The optimal method for cell delivery is not clear, and various experimental and clinical studies have employed intramyocardial, transendocardial, intravenous, intracoronary, and retrograde coronary venous injections. In experimental myocardial infarction, functional improvements have been achieved after transplantation of a variety of different cell types, including ES cells, HSCs, MSCs, USCs, and ASCs. Early studies suggested that each of these cell types might have the potential to engraft and generate cardiomyocytes. However, most investigators have found that the generation of new cardiomyocytes by these cells is at best a rare event and that graft survival over long periods is poor. The preponderance of evidence suggests that the observed beneficial effects of most experimental therapies were not derived from direct stem cell generation of cardiomyocytes but rather from indirect effects of the stem cells on resident cells. It is not clear whether these effects reflect the release of soluble trophic factors, the induction of angiogenesis, the release of anti-inflammatory cytokines, or another mechanism. A wide variety of cell delivery methods, cell types, and cell doses have been used in a progressively enlarging series of clinical trials, but the fate of the cells and the mechanisms by which they alter cardiac function are still open questions. A number of studies have shown a small but measurable improvement in cardiac function and, in some cases, reduction in infarct size. Further, some studies have reported that transplantation of bone marrow–derived stem cells improved outcome for patients in heart failure. However, in aggregate, the clinical benefits of stem cell therapy have been small and inconsistent. Moreover, the available evidence suggests that beneficial clinical effects, if any, reflect an indirect effect of the transplanted cells rather than cell replacement. However, genuine cell replacement may become possible as new protocols are being developed for generating cardiomyocytes from pluripotent and multipotent stem cells.

Diabetes Successes with islet cell and pancreas transplantation have provided proof of concept for cell-based therapies for type 1 diabetes. However, the demand for donor pancreases far exceeds the number available, and maintenance of long-term graft survival remains a problem. The search for a renewable source of stem cells capable of regenerating pancreatic islets has therefore been intensive. Pancreatic beta cell turnover occurs even in the normal pancreas, although the source of the new beta cells remains controversial. This persistent turnover suggests that, in principle, it should be possible to develop strategies for reconstituting the beta cell population in diabetics. Attempts to devise techniques for promoting endogenous regenerative processes by using combinations of growth factors, drugs, and gene therapy have failed thus far, but this remains a potentially viable approach.

A number of different cell types are candidates for use in stem cell replacement strategies, including iPS cells, ES cells, hepatic progenitor cells, pancreatic ductal progenitor cells, and MSCs. Successful therapy will depend on the development of a source of cells that can be amplified to produce large numbers of progeny with the ability to synthesize, store, and release insulin when it is required, primarily in response to changes in the ambient level of glucose. The proliferative capacity of the replacement cells must be tightly regulated to avoid excessive expansion of beta cell numbers and the consequent development of hyperinsulinemia/hypoglycemia; moreover, the cells must withstand immune rejection. Several strategies are being examined for preventing immune rejection including encapsulation of the cells, elimination of HLA genes, and expression of checkpoint inhibitors. ES and iPS cells can be differentiated into cells that produce insulin, and implants of these cells can normalize blood glucose levels in diabetic animals. Clinical trials of encapsulated ES cell–derived pancreatic progenitor cells are currently in progress.

During embryogenesis, the pancreas, liver, and gastrointestinal tract are all derived from the anterior endoderm, and transdifferentiation of pancreas to liver and vice versa has been observed in a number of pathologic conditions. There is also substantial evidence that multipotential stem cells reside within gastric glands and intestinal crypts. These observations suggest that hepatic, pancreatic, and/or gastrointestinal precursor cells may be reasonable candidates for cell-based therapy for diabetes, although it is unclear whether insulin-producing cells derived from pancreatic stem cells or liver progenitors can be expanded in vitro to clinically useful numbers. MSCs and neural stem cells both reportedly have the capacity to generate insulin-producing cells, but there is no convincing evidence that either cell type will be clinically useful. Clinical trials of MSCs, USCs, HSCs, and ASCs in both type 1 and type 2 diabetes are ongoing.

Nervous System Substantial progress has been made in the development of methodologies for generating neural cells from different stem cell populations. Human ES or iPS cells can be induced to generate cells with the properties of neural stem cells, and these cells in turn give rise to neurons, oligodendroglia, and astrocytes. Reasonably large numbers of these cells can be transplanted into the rodent brain with formation of appropriate cell types and no tumor formation. Multipotent stem cells present in the adult brain also can be easily amplified in number and used to generate all the major neural cell types, but the need for invasive procedures to obtain autologous cells is a major limitation. Fetal neural stem cells derived from miscarriages or abortions are an alternative but raise ethical concerns. Nevertheless, clinical trials of fetal neural stem cells have commenced in ALS, stroke, and several other disorders. Transdifferentiation of MSCs and ASCs into neural stem cells, and vice versa, has been reported by numerous investigators, and clinical trials of such cells have begun for a number of neurologic diseases. Clinical trials of a conditionally immortalized human cell line and of USCs in stroke are also in progress. Because of the incapacitating nature of neural disorders and the limited endogenous repair capacity of the nervous system, clinical trials of stem cells in neurologic disorders have been particularly numerous, including trials in SCI, multiple sclerosis, epilepsy, Alzheimer's disease, ALS, acute and chronic stroke, numerous genetic disorders, traumatic brain injury, Parkinson's disease, and others. In diseases such as ALS, possible benefits are more likely to be due to indirect trophic effects than to neuron replacement. In Parkinson's disease, the major motor features of the disorder result from the loss of a single cell population: dopaminergic neurons within the substantia nigra; this circumstance suggests that cell replacement should be relatively straightforward. However, two clinical trials of fetal nigral transplantation failed to meet their primary endpoint and were complicated by the development of dyskinesia. Transplantation of stem cell–derived dopamine-producing cells offers a number of potential advantages over the fetal transplants, including the ability of stem cells to migrate and disperse within tissue, the potential for engineering regulatable release of dopamine, and the ability to engineer cells to produce factors that will enhance cell survival. Clinical trials of iPSC- and ESC-derived dopaminergic neuron precursors are in progress, but the experiences with fetal transplants point out the difficulties that may be encountered.

At least some of the neurologic dysfunction after SCI reflects demyelination, and both ES cells and MSCs can facilitate remyelination after experimental SCI. Clinical trials of MSCs in this disorder have commenced in a number of countries, and SCI was the first disorder targeted for the clinical use of ES cells. The first trial of ES cell–derived oligodendroglial progenitor cells in SCI was terminated early for nonmedical reasons, but another trial has commenced. At present, no population of transplanted stem cells has been shown to have the capacity to generate neurons that extend axons over long distances to form synaptic connections (as would be necessary for replacement of upper motor neurons in ALS, stroke, or other disorders). For many injuries, including SCI, the balance between scar formation and tissue repair/regeneration may prove to be an important consideration. For example, it may ultimately prove necessary to limit scar formation so that axons can reestablish connections.

Liver Liver transplantation is currently the only successful treatment for end-stage liver diseases, but the shortage of liver grafts limits its application. Clinical trials of hepatocyte transplantation demonstrate its potential as a substitute for organ transplantation, but this approach is limited by the paucity of available cells. Potential sources of stem cells for regenerative strategies include endogenous liver stem cells (such as oval cells), ES cells, MSCs, and USCs. Although a series of studies in humans as well as animals suggested that transplanted MSCs and HSCs can generate hepatocytes, fusion of the transplanted cells with endogenous liver cells, giving the erroneous appearance of new hepatocytes, appears to be the underlying event in most circumstances. The available evidence suggests that transplanted HSCs and MSCs can generate hepatocyte-like cells in the liver only at a very low frequency, but there are beneficial consequences presumably related to indirect paracrine effects. ES cells can be differentiated into hepatocytes and transplanted in animal models of liver failure without the formation of teratomas. Clinical trials are in progress in cirrhosis with numerous cell types, including MSCs, USCs, HSCs, and ASCs.

Other Organ Systems and the Future The use of stem cells in regenerative strategies has been studied for many other organ systems and cell types, including skin, eye, cartilage, bone, kidney, lung, endometrium, vascular endothelium, smooth muscle, and striated muscle, and clinical trials in these and other organs are ongoing. In fact, the potential for stem cell regeneration of damaged organs and tissues is virtually limitless. However, numerous obstacles must be overcome before stem cell therapies can become a widespread clinical reality. Only HSCs have been adequately characterized by surface markers so that they can be unambiguously identified, a prerequisite for reliable clinical applications. The pathways for differentiating stem cells into specific cellular phenotypes are largely unknown, and the ability to control the migration of transplanted cells or predict the response of the cells to the environment of diseased organs is presently limited. Some strategies may employ the coadministration of scaffolding, artificial extracellular matrix, and/or growth factors to orchestrate differentiation of stem cells and their organization into appropriate constituents of the organ. There is currently no way to image stem cells in vivo after transplantation into humans, and it will be necessary to develop techniques to do so. Fortunately, stem cells can be engineered before transplantation to contain a contrast agent that may make in vivo imaging feasible. The potential for tumor formation and the problems associated with immune rejection are impediments, and it will also be necessary to develop techniques for ensuring vascularization of regenerated tissues. There already are many strategies for supporting cell replacement, including coadministration of vasoactive endothelial growth factor to foster vascularization of the transplant. Some strategies also include the genetic engineering of stem cells with an inducible suicide gene so that the cells can be easily eradicated in the event of tumor formation or another complication. The potential for stem cell therapies to revolutionize medical care is extraordinary, and disorders such as myocardial infarction, diabetes, and Parkinson's disease, among many others, are potentially curable by such therapies.

However, stem cell–based therapies are still at a very early stage of development, and perfection of techniques for clinical transplantation of predictable, well-characterized cells is going to be a difficult and lengthy undertaking.

ETHICAL ISSUES

Stem cell therapies raise ethical and socially contentious issues that must be addressed in parallel with the scientific and medical opportunities. Society has great diversity with respect to religious beliefs, concepts of individual rights, tolerance for uncertainty and risk, and boundaries for how scientific interventions should be used to alter the outcome of disease. In the United States, the federal government has authorized research using existing human ES cell lines but still restricts the use of federal funds for developing new human ES cell lines. Ongoing studies of existing lines have indicated that they develop abnormalities with time in culture and that they may be contaminated with mouse proteins. These findings highlight the need to develop new human ES cell lines. As noted above, ES cells may be derived from unfertilized oocytes by parthenogenesis, but there is debate about whether this alters the ethical issues. The development of iPS cell technology may lessen the need for deriving new ES cell lines, but it is still not clear whether the differences in gene expression by ES and iPS cells are important for potential clinical use.

In considering ethical issues associated with the use of stem cells, it is helpful to draw from experience with other scientific advances, such as organ transplantation, recombinant DNA technology, implantation of mechanical devices, neuroscience and cognitive research, in vitro fertilization, and prenatal genetic testing. These and other precedents have pointed to the importance of understanding and testing fundamental biology in the laboratory setting and in animal models before applying new techniques in carefully controlled clinical trials. When these trials occur, they must include full informed consent and careful oversight by external review groups.

Ultimately, there will be medical interventions that are scientifically feasible but ethically or socially unacceptable to some members of a society. Stem cell research raises fundamentally difficult questions about the definition of human life, and it has raised deep fears about the ability to balance issues of justice and safety with the needs of critically ill patients. Health care providers and experts with backgrounds in ethics, law, and sociology must help guard against the premature or inappropriate application of stem cell therapies and the inappropriate involvement of vulnerable population groups. However, these therapies offer important new strategies for the treatment of otherwise irreversible disorders. An open dialogue among the scientific community, physicians, patients and their advocates, lawmakers, and the lay population is critically important to raise and address important ethical issues and balance the benefits and risks associated with stem cell transfer.

485 The Role of Circadian Biology in Health and Disease

Jonathan Cedernaes, Kathryn Moynihan Ramsey, Joseph Bass

Circadian rhythms are anticipatory, circa 24-h, autonomous cycles of physiology and behavior. These evolutionarily-conserved rhythms have evolved at both the cell and tissue level to synchronize organismal function in anticipation of the 24-h rotation of the Earth. A common feature of modern "24/7" life is the routine disruption of these endogenous circadian cycles due to the rise in shift work, jet travel across time zones, exposure to blue light–emitting devices at night, and disrupted sleep-wake behavior. In-depth characterization of the molecular basis of circadian disorders has generated novel avenues for research on how sleep-wake disruption has been associated with aging, metabolic disease, inflammation, and cancer. This chapter provides an overview of (1) the basic biology of the circadian system; (2) primary circadian rhythm and interrelated sleep disorders; and (3) the role of the circadian system in both normal human physiology and disease states. We also include an overview of how the emerging field of chronobiology may impact drug action. A glossary of terms used in circadian biology is summarized in **Table 485-1**.

BASIC EVOLUTION AND STRUCTURE OF THE CIRCADIAN SYSTEM

Long before the emergence of multicellular life, the Earth's constant rotation around the sun gave rise to a daily cycle of light and darkness. At the emergence of the first prototypal gene involved in biological clock regulation—3.4 billion years ago in photosynthetic cyanobacteria—the period of Earth's rotation along its own axis was only 8 h. The co-occurrence in molecular evolution of the biological clock and photosynthesis hints at an interrelated and selective advantage of the clock in regulation of energetic processes. Indeed, biological clocks coordinate oxygenic reactions with periods of sunlight each day, and perturbation of clock cycles reduces fitness, reproduction, and survival. Additionally, clocks protect photosynthetic organisms from the DNA-damaging effects of sunlight by timing the production of DNA repair processes, such as photolyase-mediated repair, to the nighttime. Across billions of years of evolution, as day length has gradually extended to today's circa 24 h, highly conserved circadian clocks (from *circa diem*, meaning "about a day") have been found in all photosensitive organisms, governing a wide range of biochemical, physiologic, and behavioral processes. A defining property of the circadian clock system is that it enables organisms to anticipate, rather than simply react to, daily changes in the external environment that are tied to the day-night cycle. In mammals, circadian systems are organized hierarchically with a light-responsive "master" circadian pacemaker located within the suprachiasmatic nucleus (SCN) of the anterior hypothalamus, which in turn presides over a network of both extra-SCN and peripheral clocks (see "Anatomic Organization of the Circadian Clock Network," below). Daily light exposure signals to the SCN and entrains the circadian system to the 24-h day (see "Entrainment and Measurement of the Circadian System," below). In turn, the SCN maintains synchrony of a diverse network of both central and peripheral clocks via a variety of signals that have as yet to be fully identified. These signals involve direct physiologic rhythms (core body temperature), the autonomic nervous system, and neuroendocrine signals, including cortisol as part of the hypothalamic-pituitary-adrenal (HPA) axis.

MOLECULAR ORGANIZATION OF THE MAMMALIAN CIRCADIAN CLOCK

At the molecular level, mammalian circadian rhythms are generated by a transcription-translation autoregulatory feedback loop. The forward

TABLE 485-1 Glossary of Terms Used in Discussion of the Circadian System

TERM	DESCRIPTION
ASPD	Advanced sleep phase disorder (see text for description).
CBT	Core body temperature. Often used as an indicator of the circadian rhythm, but can be masked by sleep and exercise.
CCGs	Clock-controlled genes; output of the molecular clock.
Chronotype	Internal circadian rhythm of an individual determined by phase of entrainment, determining sleep propensity and timing of maximum alertness over a 24-h period.
Circadian period	Time required for one complete cycle or oscillation. Calculated by the time distance between two consecutive peaks or troughs of a circadian variable.
Circadian phase	Timing of the circadian rhythm. Defined by comparing, e.g., the peak (acrophase) or trough (bathyphase) to a fixed event, e.g., to a point in time. Synonymous with phase angle.
Circadian rhythm	A biological process that exhibits an endogenous, entrainable oscillation of ~24 h.
Circadian rhythm sleep disorders	Disorders of multiple etiology that have in common that they result in maladjustment of the biological clock with respect to the environment.
Constant routine	An experimental paradigm designed to study endogenous circadian rhythms in humans, by keeping behavioral and environmental factors constant. These paradigms thereby typically entail a combination of constant dim lighting, evenly distributed isocaloric energy intake, semirecumbent posture, and forced extended wakefulness.
Desynchrony	Loss of synchrony occurring either between a rhythm and its zeitgeber (external, "time giver" signal) or between two or more rhythms within an organism (internal).
Diurnal rhythm	An oscillation synchronized with the day/night cycle that repeats itself with a 24-h period. The rhythm does not have to persist when time cues (e.g., light) are absent.
DLMO	Dim-light melatonin onset; a marker of melatonin rhythm.
DSPD	Delayed sleep phase disorder (see text for description).
Entrainment	Synchronization of a circadian rhythm or other self-sustaining oscillation by a factor—zeitgeber—that enforces the oscillator. Constant entrainment between the zeitgeber and the oscillator results in a stable phase relationship between these entities.
Infradian rhythm	A recurrent cycle or period with a period length significantly greater than 24 h.
Melatonin	Hormone produced by the pineal gland (chemical name *N*-acetyl-5-methoxytryptamine); derived from L-tryptophan. Various forms of melatonin can be prescribed for circadian rhythm sleep disorders or sleep disorders.
Non-24-h rhythm disorder	A syndrome in which there typically are chronic 1- to 2-h daily delays in sleep onset and wake times in an individual living in society, e.g., due to complete blindness.
Peripheral clocks	Clocks presiding outside of the suprachiasmatic nucleus, the circadian system's master pacemaker.
PRC	Phase response curve; visual representation of how a particular manipulation (e.g., light) produces phase shifts as a function of the phase (i.e., circadian time) at which the manipulation occurs. Defining the PRC to light has enabled researchers to understand and predict how entrainment to light cycles is accomplished.
SCN	The suprachiasmatic nucleus or nuclei, also known as the master pacemaker in mammalian species. A bilateral set of nuclei positioned in the anterior ventral hypothalamus. Essential for entraining extra-SCN central and peripheral oscillators to the prevailing light-dark cycle via photic input from the retina.
Shift work	Work scheduled so that it occurs outside of the traditional work schedule of 9:00 A.M. to 5:00 P.M., or 6:00 A.M. to 6:00 P.M., depending on definition. Various forms of shift work exist, such as early morning, evening, or night shifts, as well as rotating shifts.
Ultradian rhythm	A recurrent cycle or period with a period significantly shorter than 24 h—e.g., a 2-h rhythm would exhibit 12 cycles within a circadian (24-h) rhythm.

limb of the clock is composed of the basic helix-loop-helix transcription factors (TFs) CLOCK (or its paralogue, NPAS2) and BMAL1. These drive expression of their own repressors (PER and CRY) in the negative limb in a cycle that repeats itself every 24 h **(Fig. 485-1)**. A second short feedback loop involves CLOCK/BMAL1-mediated transcription of the retinoic acid–related orphan nuclear receptor families ROR and REV-ERB, which activate and repress *Bmal1* transcription, respectively. Rhythmic posttranslational regulation of the stability and degradation of core clock TFs occurs via events such as phosphorylation by casein kinase 1 epsilon (CK1ε) and casein kinase 1 delta (CK1δ) and ubiquitination by FBXL3 and FBXL21. In addition to the circa 24-h oscillation of core clock genes, a wide array of downstream clock-controlled genes (CCGs) exhibit broad rhythmic amplitude in expression, ultimately giving rise to rhythmic physiologic processes.

The importance of localized clock gene expression has been demonstrated by genetic animal studies, such as with targeted ablation of *Bmal1*, the only clock gene that lacks a known functional paralog. Deletion of *Bmal1* either in the whole brain or in regions that span the brain region that coordinates circadian rhythms—the SCN—cause behavioral arrhythmicity, even when genetic ablation occurs in adult life. Conversely, restoring *Bmal1* expression specifically in brain in adult CLOCK mutant mice rescues behavioral locomotor rhythms. Of note, whereas the protein CLOCK normally heterodimerizes with BMAL1, NPAS2 is able to functionally substitute for CLOCK within the pacemaker neurons; thus, while mice lacking either *Clock* or *Npas2* genes maintain rhythmicity, mutants lacking both CLOCK and NPAS2 lack circadian rhythms in locomotor activity.

A major transformation in our understanding of circadian biology came with the discovery that the molecular clock network is present not only in the SCN but also within most peripheral tissues, as well as in extra-SCN neurons in the brain. In primates, ~82% of all protein-coding transcripts exhibit daily (sleep-wake) rhythms in some tissue or other. In rodents studied under constant conditions, ~3–16% of the transcriptome in a given tissue displays 24-h rhythms in mRNA expression levels, even though the repertoire of such genes varies substantially between tissues, in accordance with tissue-specific functions. The core clock feedback loop and the induction of transcriptional CCG rhythms also involves epigenetic mechanisms such as conformational chromatin dynamics, histone acetylation, and DNA methylation. Conversely, posttranscriptional events such as RNA polyadenylation, nuclear shuttling, and mRNA translation also exhibit circadian variation, further increasing the repertoire of rhythmic regulation at a cellular level.

ANATOMIC ORGANIZATION OF THE CIRCADIAN CLOCK NETWORK

The molecular circadian feedback loop is synchronized with sunrise each day by photosensitive melanopsin-expressing neurons within

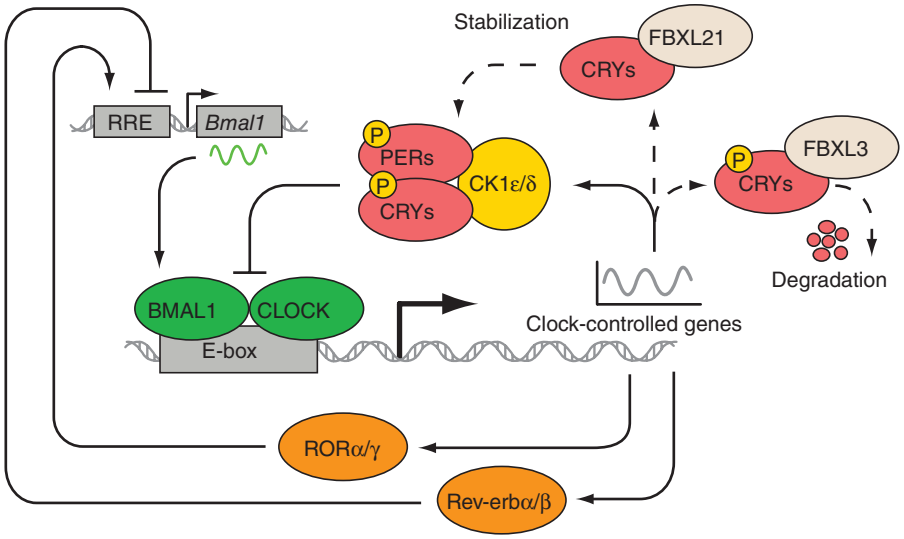

FIGURE 485-1 Central clock molecular mechanism. The core molecular clock machinery in mammals is encoded by interlocking transcription-translation feedback loops that oscillate with ~24-h periodicity. The transcription factors CLOCK and BMAL1 heterodimerize to drive transcription of downstream clock-controlled target genes containing E-box enhancer elements. Among these, the PER and CRY proteins multimerize and inhibit CLOCK/BMAL1, while RORs and REV-ERBs activate and inhibit, respectively, Bmal1 transcription, resulting in rhythmic oscillations of clock-controlled and downstream target genes.

the retina. These neurons provide input to the SCN via the retinohypothalamic tract (RHT), allowing mammals to maintain coherent organismal rhythms in line with the external light/dark cycle. Of note, mutations in several of these clock genes are associated with impaired circadian rhythms and physiology in humans (see "Primary Pathologies of the Circadian System" below).

Understanding the circuit organization of the circadian clock within the brain is increasingly relevant in understanding how the master circadian pacemaker center within the SCN regulates feeding, sleep-wake activity, endocrine processes, and energy expenditure and metabolism (Fig. 485-2). Identification of the SCN as the master pacemaker was first established by the observation that SCN lesioning induced complete loss of rhythms of locomotor activity, drinking behavior, and endocrine hormone secretion. The ventral "core" region of the SCN, which is composed of neurons producing vasoactive intestinal polypeptide (VIP), receives photic information directly from the retina through the RHT. At the molecular level, circadian gene transcription is induced within the SCN through the initial activation of immediate early genes, such as *Per1*, *Per2*, *c-fos*, and *jun*. Cells within the "core" region of the SCN then signal primarily via γ-aminobutyric acid (GABA)-ergic neurotransmitter release to synchronize the cells within the "shell" region of the SCN, which produce arginine vasopressin (AVP), the most important neuropeptide for maintaining intra-SCN synchronicity.

The SCN communicates to extra-SCN and peripheral clocks through both secreted factors and neuronal projections. The former was elegantly proven by the ability of SCN grafts to partially restore locomotor rhythms in SCN-lesioned animals. Efferent nerve outputs arise both from the AVP-producing shell region of the SCN and the VIP-predominated core. The SCN projects to several hypothalamic and thalamic regions, including the median preoptic nucleus (MPO), the subparaventricular zone (SPZ), the dorsomedial hypothalamus (DMH), the paraventricular nucleus of the hypothalamus (PVH), and the paraventricular nucleus of the thalamus (PVT). Some of these regions, in turn, regulate output to both sleep- and wake-promoting regions, as well as to regions involved in regulation of autonomic, body temperature, and hormonal rhythms, as well as feeding. The SCN is thereby thought to promote sleep in part through the transmission of neural signals that terminate in the sleep-promoting ventrolateral preoptic nucleus (VLPO), i.e., one of the brain regions that is active during sleep. In contrast, the SCN promotes wakefulness during the active phase by transmission of neural signals that—by passing through regions such as the SPZ and the DMH—terminate in wake-promoting regions, including the locus coeruleus, lateral hypothalamic nucleus, ventral tegmental area, and dorsal raphe nucleus.

The SCN also signals via noradrenergic fibers to the pineal gland, thereby regulating the circadian production of the hormone melatonin. SCN control of the nighttime rise in pineal melatonin release (in both diurnal and nocturnal animals) is mediated through a pathway involving the PVH. Of note, artificial light at night delays the secretion of melatonin, ultimately affecting sleep (see "Endocrine Systems Regulated by the Circadian Clock" below). Melatonin plays a complex role in the circadian system since the MT1 and MT2 melatonin receptors are expressed in the SCN itself; thus, melatonin feeds back to modulate circadian outputs to other cells in the brain and body.

Neuronal output from the SCN also reaches the periphery, i.e., to the adrenal glands, the liver, and the pancreas. The SCN produces rhythmic variation in multiple neuroendocrine axes, producing daily rhythms of gonadotropin, thyrotropin, and somatotropin. Prominent HPA axis rhythms ultimately give rise to daily variation in diverse pathways essential for hemodynamic stability, metabolism, and inflammation. These rhythms originate with SCN control of corticotropin-releasing hormone (CRH)–producing cells in the PVH, which may regulate sleep as well as induce daily oscillations of both pituitary adrenocorticotropic hormone (ACTH) and adrenal cortisol. Highlighting the importance of SCN output for peripheral rhythms, there is a dramatic reduction in the number of transcripts that exhibit circadian rhythms in the liver following SCN ablation in mice. Nonetheless, when the autonomous clock in the liver is ablated in mice, some key clock transcripts such as *Per2* are still able to cycle as long as the core body temperature rhythm persists. Whereas the SCN is exclusively entrained by light, meal timing is able to signal circadian time directly to peripheral tissues such as the liver. Thus, shifted meal timing as occurs during shift work or jetlag can uncouple peripheral clocks from the central pacemaker. In comparison to peripheral tissue clocks, the SCN is also resistant to phase shifts induced by temperature. This is consistent with the concept that the SCN generates the core body temperature rhythm as one of the major mechanisms to signal circadian time to peripheral clocks.

ENTRAINMENT AND MEASUREMENT OF THE CIRCADIAN SYSTEM

Under normal light-dark cycles, the circadian system is corrected or "entrained" on a daily basis, producing diurnal rhythms of 24 h. Such signals of entrainment are called zeitgebers (German for "time-giver" signals) and include light exposure, meal timing, and activity patterns. Light serves as the dominant zeitgeber for the circadian system, and a breakthrough in understanding photoentrainment in mammals came with the discovery of the melanopsin system, which is composed of a specialized class of photosensitive retinal ganglion cells that expresses

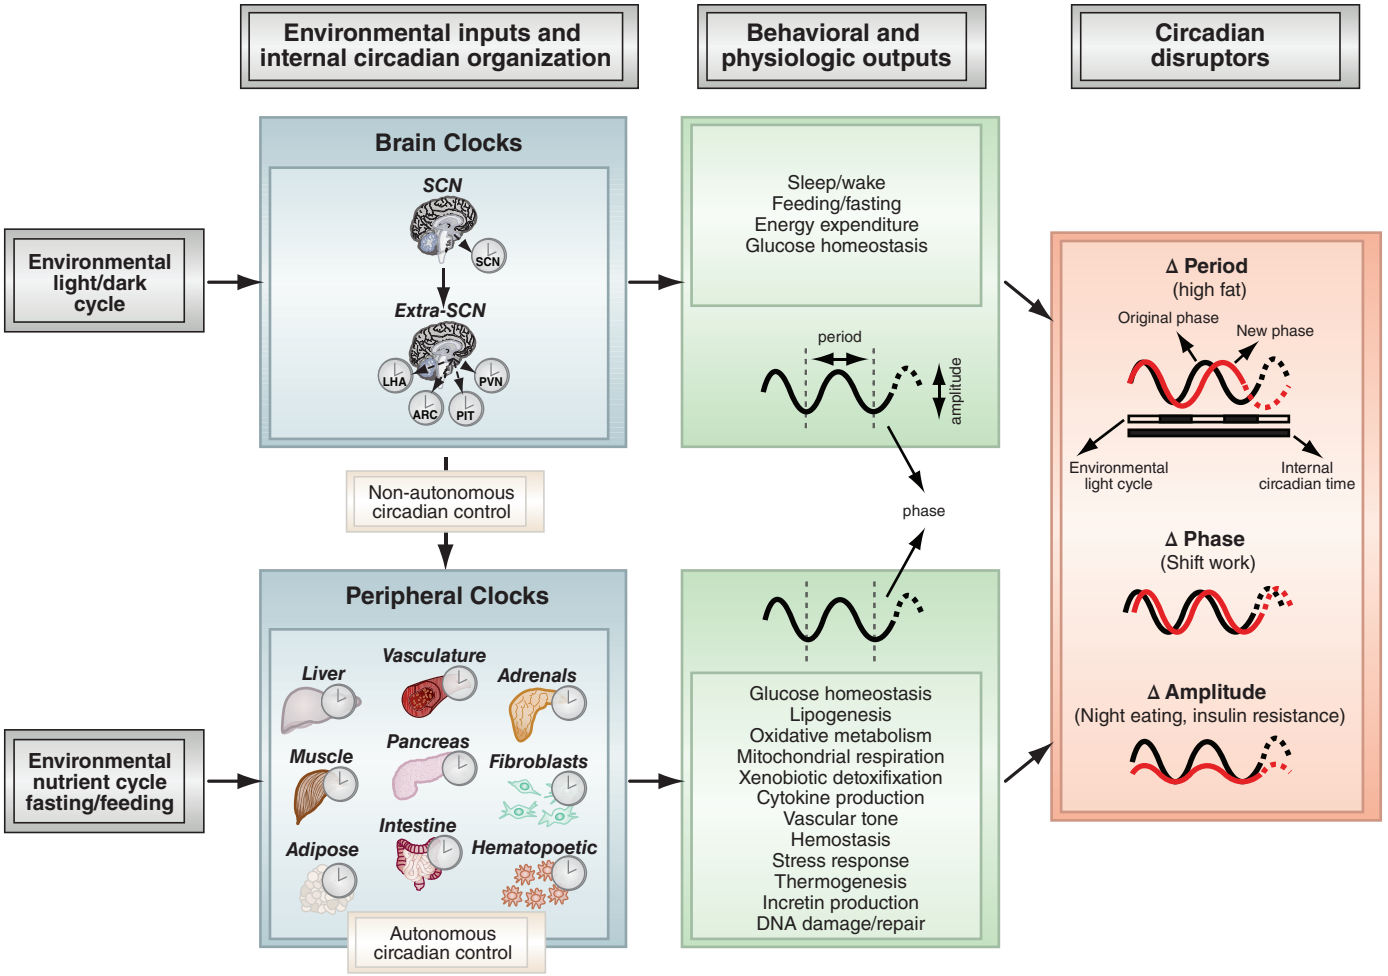

FIGURE 485-2 Central and peripheral clocks coordinate environmental cues with behavior and physiologic outputs. Light entrains the master pacemaker neurons in the suprachiasmatic nucleus (SCN), which subsequently synchronizes extra-SCN and peripheral clocks. Brain clock output includes sleep-wake, fasting-feeding, and energy expenditure cycles, while peripheral clock output includes a wide range of physiologic processes, including glucose homeostasis, oxidative metabolism, cytokine production, and stress response. The right column indicates different ways that circadian disruptors, such as diet, shift work, or other circadian rhythm sleep disorders, may impact the clock—i.e., by changing circadian period, phase, or amplitude.

the blue light–sensitive photopigment melanopsin in the inner retina, separate from the photoreceptive rods and cones. Blue light around this wavelength (~480 nm) suppresses melatonin, i.e., melatonin levels are normally low during the day, and promotes subjective and objective (electroencephalography-assessed) wakefulness.

The ability of light to entrain the circadian system functions according to a so-called phase response curve (PRC). When light exposure occurs prior to the critical phase of the core body temperature (CBT), defined by the CBT's minimum, light produces a phase delay in the circadian rhythm. Conversely, light exposure after this critical period causes phase advances. The circadian system can respond even to small changes in light intensity (e.g., dim light at ~100 lux can produce half of the phase delay compared with an almost 100-fold greater light exposure). This responsiveness has been found to be highly individual, varying several tenfold. This is in part due to genetic variation, as variants in clock genes can modulate the responsiveness of the human circadian system to light.

When an organism is placed in an environment without zeitgebers, the circadian rhythm is said to free-run, as it relies on the endogenous rhythm of the circadian system. In humans, the study of endogenous circadian rhythms can be achieved by using a so-called constant routine that eliminates the risk of masking by factors such as sleep. In these paradigms, subjects are kept awake in a constant semirecumbent posture, meals are provided on an hourly basis, light is constantly kept below the level that phase shifts the SCN, and circadian rhythms are assessed by frequently measuring CBT, melatonin, or peptidergic hormone rhythms over the course of 24 h or longer. In animals, circadian rhythms are instead studied by examining behavior and physiologic responses after 30–36 h of complete darkness, and endogenous rhythms are assessed by measuring voluntary locomotor activity. From these measurements, key properties of the circadian system can be ascertained, such as period length (peak-to-peak or trough-to-trough time), amplitude (peak-to-trough difference), and phase (timing of peak or trough in relation to a reference point) (Fig. 485-2).

These studies have revealed that the endogenous human circadian clock runs with a period length of approximately 24.2 h (compared with that of mice, which runs at ~23.5 h, depending on the strain). Evidence indicates that human females may have a slightly shorter circadian clock (24.1 vs 24.2 h), and many circadian parameters have been found to exhibit differences that are dependent on biological sex. Notably, interindividual variability in the endogenous circadian period length is further diversified by the existence of genetic polymorphisms in clock genes (see below). These gene variants can confer extremes in the endogenous circadian period as well as phase; the latter can be advanced or delayed by ~3–4 h in each direction. This is due both to altered circadian rhythms at the cell level and to altered SCN responsiveness to entrainment by light. For instance, *PER3* exists in a variable-number, tandem-repeat polymorphism. Individuals homozygous for a *PER3 5/5* genotype have been reported to be more responsive than *PER3 4/4* homozygous individuals to the melatonin-suppressing effect of evening blue light exposure.

Using specifically-developed questionnaires to establish preferred sleep-wake timing, individuals can be categorized into so-called morningness-eveningness types or chronotypes. The most commonly used questionnaires are the Horne-Östberg Morningness-Eveningness Questionnaire (MEQ) and the Munich ChronoType Questionnaire

(MCTQ). A composite MEQ score allows grouping into five categories that range from definite morning-type to evening-type individuals, for instance, based on preferred waking time. In contrast, the MCTQ centers on the midpoint of sleep as a circadian marker, queries age and sex across a range of geographical locations, and can be used to ascertain differences between socially imposed sleep patterns (e.g., on working days) and sleep patterns on free days (the difference constituting so-called social jetlag). According to MCTQs obtained from primarily European populations, ~1% of the general population goes to bed before 10:00 P.M. and ~8% after 3:00 A.M. Differences in chronotype are linked to altered circadian timing, including peak levels of melatonin, which can vary by up to 4 h between extreme morning and evening types. Extreme chronotypes have also been shown to be linked to various traits; i.e., low morningness scores have been associated with greater tolerance to shift work.

Melatonin is one of the most commonly used peripheral markers of an individual's circadian rhythm, reflecting the rhythmic function of the SCN. Circadian rhythms of melatonin can be measured in saliva or plasma, whereas 6-sulphatoxymelatonin (aMT6S), a metabolite generated from the breakdown of melatonin, can also be measured in urine. Accurate estimations of melatonin rhythms are often obtained by analyzing the dim light melatonin onset (DLMO), which as the name implies does not require an entire 24-h sampling, making this marker useful in both the clinical and research settings. In normally entrained individuals, the DLMO can be used to ascertain whether an individual's circadian rhythm is phase advanced or delayed, and this onset typically occurs ~2 h before the onset of sleep. The midpoint of sleep—the main marker used by the MCTQ—also strongly correlates with melatonin onset.

The CBT is also often utilized as an indicator of the circadian rhythm. Even though the outcome is more variable when using the CBT, it usually correlates well with the phase obtained using the melatonin rhythm. The CBT, however, can be masked by factors such as sleep, food intake, and activity. CBT can be recorded and registered wirelessly with relative ease. In humans, CBT can be recorded via rectal thermometers or probes that are swallowed to pass through the gastrointestinal tract. When humans are studied under normal conditions with normal lighting and sleep duration from 2300 to 0700 h, the CBT reaches around 37.2°C by 0900 h, and from there, it continues to rise slowly until it reaches 37.4°C around 11 h later. The CBT then drops to the daily low of 36.5°C in the early morning (0400 h).

Given the interrelationship between the circadian system and sleep-wake systems, researchers have developed paradigms that uncouple the circadian system from sleep-wake states, enabling the study of the contribution of the circadian system to investigated parameters across the entire sleep-wake cycle. These paradigms are known as "forced desynchrony" protocols and involve enforcing a significantly shortened (e.g., 20 h) or prolonged (e.g., 28 h) day length upon individuals. These protocols thus attempt to approximate what occurs during rotating shift work or "jetlag," e.g., when travel across several time zones suddenly shifts the light-dark and behavioral cycles drastically away from the entrained 24-h rhythm. As described below, forced desynchrony protocols have contributed to uncovering how the circadian system regulates parameters such as cognitive performance, subjective alertness, and metabolic and cardiovascular health.

PRIMARY PATHOLOGIES OF THE CIRCADIAN SYSTEM

An overarching term for disorders of the circadian system is *circadian rhythm sleep disorders* (CRSDs). Several of these disorders are quite common and have become increasingly recognized as important factors in a number of conditions. A unifying feature of CRSDs involves a mismatch between subjective behavioral and physiologic rhythms with the environmental light-dark or social activity-rest cycles (i.e., the body clock is out of sync with the external light-dark cycle). CRSDs can arise either due to misalignment of an exogenous environmental factor, such as light, with the intrinsic circadian cycle or due to misalignment of the activity-rest cycle in relation to endogenous circadian timing (e.g., shift work or jetlag). In addition to such environmental or exogenous conditions causing circadian disruption, in some cases, intrinsic circadian timing is altered in relation to the external environment, as in the case of endogenous circadian disorders such as those caused by mutations in core clock genes. Under conditions of intrinsic circadian abnormalities, it is often exceedingly difficult for individuals suffering from CRSDs to try to properly realign themselves, and these disorders often result in adverse effects such as excessive sleepiness or depressed mood. Societal and economic consequences are also common; these can result in the individual being unable to maintain a job or attend school at regular hours. The criteria for CRSDs based on the International Classification of Sleep Disorders (ICSD) are shown in **Table 485-2**.

TABLE 485-2 Criteria for Circadian Rhythm Sleep Disorders

CRITERIA	DESCRIPTION
A	A persistent or recurrent pattern of sleep disturbance due primarily to one of the following: • Alterations of the internal circadian timekeeping system. • Misalignment between endogenous circadian rhythms and exogenous factors that affect the timing or duration of sleep.
B	A circadian-related sleep disruption that leads to insomnia, excessive daytime sleepiness, or both.
C	A sleep disturbance that is associated with impairment of social, occupational, or other areas of functioning.

Animal models have greatly advanced our understanding of how core molecular clock components contribute to maintaining normal sleep-wake/rest-activity cycles **(Table 485-3)**. For example, *Clock*$^{\Delta 19/\Delta 19}$ mice have reduced total sleep duration and less induction of rapid eye movement (REM) sleep in response to sleep deprivation. Further, mice that lack *Bmal1* have increased total sleep time, but it is more fragmented and lacks clear 24-h sleep-wake rhythms, and mice lacking the repressors *Cry1* and *Cry2* are not only arrhythmic but spend more time in non-REM sleep. Finally, while ablation of the circadian gene *Dbp* does not alter the specific duration of sleep stages, it does lead to an altered circadian sleep-wake distribution, with more sleep during the normal wake period and vice versa. Consistent with a key role of clock genes in regulating sleep-wake behavior, human genetic studies of twins have found that up to half of the variation in diurnal preference is heritable. Established genetic variants associated with diurnal preference and circadian sleep disorders are listed in **Table 485-4**.

Delayed Sleep Phase Disorder Delayed sleep phase disorder (DSPD; or delayed sleep-wake phase disorder [DSWPD]) is one of the more common circadian rhythm sleep disorders. The true prevalence is not fully known but may range from 0.2–16% depending on definition used, and the condition is more common in younger age groups. DSPD is characterized by chronic and significant delays in both sleep onset and wake times compared to normal "socially acceptable" sleep-wake hours (i.e., scoring as "extreme night owls" on morningness-eveningness preference tests). Rhythms of parameters, such as CBT and melatonin levels in plasma and urine, are likewise often delayed, and the circadian period (tau) may be longer in DSPD. Onset of DSPD most commonly occurs during adolescence or early adulthood. While the precise etiology of DSPD is not well established, it has been associated with polymorphisms within the circadian clock genes *CLOCK, PER3,* and *CRY1*. As an example, the latter mutation has been observed at a frequency of ~0.6%. An integrated behavioral and pharmaceutical therapeutic approach has been found to be most effective at treating individuals with DSPD. Such treatments include a combination of bright-light therapy soon after waking in the morning (and/or dark-room therapy in the evening) and melatonin administration in the evening several hours prior to the onset of sleep. These approaches aim to realign endogenous circadian rhythms with the desired sleep-wake schedule. As individuals suffering from DSPD also phase delay more rapidly, this explains why attempts to phase advance their sleep schedule can be difficult, as well as why relapse can easily occur after initial treatment.

TABLE 485-3 Animal Models of Genetic Circadian Disruption

GENE	AVERAGE CIRCADIAN TIME OF PEAK TRANSCRIPT LEVEL		ALLELE	MUTANT PHENOTYPE
	SCN	PERIPHERY		
Bmal1 (Arntl)	15–21	22–2	*Bmal1*$^{-/-}$	Arrhythmic
CK1δ (Csnk1δ)	No rhythm	No rhythm	*Csnk1δ*$^{-/-}$	0 to 0.5-h shorter period
CK1ε (Csnk1ε)	No rhythm	No rhythm	*CK1ε*^{tau}	4-h shorter period
CK1ε	—	—	*CK1ε*$^{-/-}$	0.2- to 0.4-h longer period
Clock	No rhythm	21–3	*Clock*$^{-/-}$	0.5-h shorter period
—	—	—	*Clock*$^{\Delta 19/\Delta 19}$	4-h longer period/arrhythmic
Clock/Npas2	—	—	*Clock*$^{-/-}$*/NPAS2*$^{-/-}$	Arrhythmic
Cry1	8–14	14–18	*Cry1*$^{-/-}$	1-h shorter period
Cry2	8–14	8–12	*Cry2*$^{-/-}$	1-h longer period
—	—	—	*Cry2*^{A260T}	0.2-h shorter period
Dbp	—	—	*Dbp*$^{-/-}$	0.5-h shorter period
Npas2	N/A	0–4	*Npas2*$^{-/-}$	0.2-h shorter period
Per1	4–8	10–16	*Per1*$^{-/-}$	0.7-h shorter period
—	—	—	*Per1*^{brdm1}	1-h shorter period
—	—	—	*Per1*^{ldc}	0.5-h shorter period/arrhythmic
Per2	6–12	14–18	*Per2*^{brdm1}	1.5-h shorter period/arrhythmic
—	—	—	*Per2*^{ldc}	Arrhythmic
Per3	4–9	10–14	*Per3*$^{-/-}$	0 to 0.5-h shorter period
Rev-erbα (Nr1d1)	2–6	4–10	*Rev-erbα*$^{-/-}$	0.5-h shorter period/disrupted photic entrainment
Rorα	6–10	Arrhythmic/various	*staggerer*	0.5-h shorter period/disrupted photic entrainment
Rorβ	4–8	18–22	*Rorβ*$^{-/-}$	0.5-h longer period
Rorγ	N/A	16–20/various	*Rorγ*$^{-/-}$	Normal behavior

Note: Normal circadian rhythms of circadian clock and related genes, with description of circadian phenotype in mutant mice.

Advanced Sleep Phase Disorder Another circadian rhythm sleep disorder whereby one gets the correct amount and quality of sleep but at a shifted time is advanced sleep phase disorder (ASPD; or advanced sleep-wake phase disorder [ASWPD]). The prevalence of this disorder may be <1%, but the condition may be underreported, given that it may cause fewer conflicts with societal demands (i.e., 9-to-5 schedules) compared with conditions such as DSPD. Individuals with ASPD experience an advance in their major sleep episode in relation to the desired sleep-wake times. Thus, this disorder typically results both in very early evening bedtimes and morning awakenings (e.g., "extreme early birds"), resulting in reduced quality of life due to excessive sleepiness during the early evening, even in social situations. Individuals with ASPD also have phase-advanced temperature and melatonin rhythms in parallel with their earlier sleep onsets. ASPD occurs more often in older individuals, although early-onset autosomal dominant familial variants (familial advanced sleep phase syndrome [FASPS]) have also been associated with mutations in either the *PER2* or the casein kinase 1δ (*CK1δ*) gene. *PER2* is critical for SCN resetting by light, and the identification of *PER2* mutations in familial ASPD was the first instance in which clock genes were tied to a CRSD. Such mutations have been found to shorten the endogenous circadian period to ~23.3 h compared with the normal 24.2-h period length. Accordingly, ASPD can be distinguished from other noncircadian sleep disorders by an early onset of dim-light melatonin secretion. Similar to DSPD, polysomnography and actigraphy are not required for diagnosing ASPD, although actigraphy, preferably for 14 days or longer, may be significantly more feasible for long-term analysis of circadian timing of sleep. Treatments for ASPD include bright light or blue-enriched

TABLE 485-4 Mutations and Gene Variants Linked to Sleep-Wake Disorders and Diurnal Preference

GENE	POSITION	POPULATION	SYNDROME/SLEEP PREFERENCE
h*CKIε*	S408N	Japanese	Protection against DSPS
h*CKIγ*	T44A	Pedigree	FASPS
h*CKIΔ*	H46R	Pedigree	FASPS
h*CLOCK*	T3111C (3′-UTR)	European	Eveningness
h*CRY2*	A260T	Pedigree	FASPS
h*PER2*	S662G (missense mutations in CKIε binding region)	Pedigree	FASPS
h*PER2*	C111G (5′-UTR)	British	Extreme morningness
h*PER3*	P415A/H417R	Pedigree	FASPS and seasonal affective disorder

h*VIP*	rs9479402 (gene variant 54 kb upstream of VIP)	European (>97% European ancestry)	Morningness

Abbreviations: DSPS, delayed sleep phase syndrome; FASPS, familial advanced sleep phase syndrome.

phototherapy in the evening hours to delay the phase of the circadian clock to a later hour.

Shift Work Sleep Disorder Given the increased prevalence of shift work in today's 24/7 society and the accumulating evidence for increased incidence of sleep and metabolic disorders, including obesity, type 2 diabetes, cardiovascular disease, and cancer, in shift workers, the need to develop effective treatments for shift work sleep disorder (SWSD) is increasingly important. SWSD is at its core defined by the primary symptom of either insomnia or excessive sleepiness, arising as a result of work that usually is scheduled during the habitual hours of sleep or comprises irregular work hours. The symptoms may result from recovery of sleep having to consume a large proportion of the individual's free time, which may produce negative social consequences such as difficulties maintaining social relationships. Older individuals are typically at an increased risk of SWSD due to age-associated decline in the ability to maintain sleep during the time of day that would normally constitute the wake period. Since the symptoms likely arise from a misalignment of sleep-wake rhythms with the external light-dark cycle, therapeutic approaches aim to realign endogenous circadian rhythms with the sleep cycles dictated by work. In addition to optimizing the sleep environment at home to minimize disruptions, timed bright light therapy can help individuals with SWSD—i.e., for night workers, intermittent bright light exposure during the night and avoidance of bright light during the morning, even on days off, has been shown to improve sleep and feelings of alertness. Melatonin prior to bedtime may also help improve symptoms of SWSD. Genetic screening combined with chronotype questionnaires may become useful tools for determining whether a given individual is suited for shiftwork. For instance, a twin study indicated that a genetic variant of the circadian gene *DEC2* was associated with reduced sleep duration and shorter recovery sleep following extended sleep deprivation. More studies may reveal additional genetic variants that confer an advantage to repeated phase advances and phase delays as typically occurs in shift work.

Irregular Sleep-Wake Rhythm Damage to the SCN can produce arrhythmicity in animals and is thought to be one of the possible underlying reasons for the temporally disorganized sleep-wake pattern that characterizes the disorder known as irregular sleep-wake rhythm (ISWR). Other contributing factors may be a reduced responsiveness to entraining signals such as light and physical activity, as well as a decreased exposure to such signals as often occurs with increasing age due to, for example, increased risk of poor health and impaired mobility. Whereas the total sleep time per 24 h may be comparable, there is a relative absence of a circadian pattern to the sleep-wake cycle. Sleep timing throughout the sleep-wake cycle can be shortened—sometimes close to randomly distributed—instead of occurring in several distinct bouts. ISWR is often associated with neurologic impairment, foremost Alzheimer's disease in older age; however, ISWR can also occur in individuals with poor sleep hygiene. The most effective treatments for ISWR involve not pharmacotherapy, but rather multimodal interventions such as increased light exposure, improved sleep hygiene, and promotion of social and physical activities.

Non-24-h Sleep-Wake Rhythm Disorder Individuals with non-24-h sleep-wake rhythm disorder ("non-24"), otherwise known as free-running disorder (FRD), have endogenous circadian rhythms that are not synchronized with the external 24-h day-night cycle due to an inability to readjust the circadian clock to the 24-h day on a daily basis. This most commonly occurs in individuals who are completely blind (i.e., lacking all photoreceptors) since they are unable to respond to light cues that normally would reset the endogenous circadian clock on a daily basis (although the condition has also been reported in sighted individuals). Instead, the sleep-wake period length corresponds to the individual's endogenous circadian rhythms, which are typically slightly longer than 24 h, thereby shifting sleep and wake cycles over time in relation to the light-dark cycle. Instead of sleeping at the same time each day, their sleep time would gradually be delayed each day until their sleep period literally goes "around the clock." Depending on the individual's endogenous rhythm, the individual will take a given number of days to realign his or her endogenous phase (in a 360° phase plot) with the zero time point in the exogenous 24-h light-dark cycle. For example, if an individual has an endogenous 24.5-h rhythm, it would take that individual 48 days to cycle from one cycle to the next. Because of this chronic cycling, prominent symptoms of non-24 include sleep-wake cycle disruption (insomnia and daytime sleepiness), impaired alertness and mood levels, and severe difficulties partaking in normally scheduled work, school, or social activities. Non-24 can be diagnosed following diurnal analysis of an individual's melatonin or cortisol rhythms, in combination with analyses of sleep diaries where the sleep onset and offset can be visualized over time to identify the free-running period. Treatments for sighted non-24-h patients include a combination of bright light therapy with appropriately timed melatonin administration, whereas melatonin and dual melatonin (MT1 and MT2) receptor agonist administration in completely blind non-24-h patients has been shown to entrain free-running rhythms and improve symptoms.

Jetlag Most have experienced symptoms associated with jetlag, including insomnia, daytime sleepiness, and fatigue, when traveling from one time zone to another, as one's endogenous circadian rhythms are not yet aligned, or entrained, to the new external light-dark cycle. This is due to the slowness of the circadian system to adapt to the new time zone: typically, the human circadian system is able to shift up to ~1.5 h a day in the westward direction (i.e., a phase delay), whereas it shifts more slowly (up to ~1 h daily) with eastward direction of travel (i.e., achieving a phase advance). Importantly, the symptoms are distinguished from the more short-lived symptoms that can partially result from exposure to traditional airplane cabin conditions, including abdominal distention, dependent edema, muscle cramps, headaches, nausea, and intermittent dizziness. Usually, symptoms of jetlag abate within the first couple of days after traveling and may present themselves after a first night of good sleep (which is more dependent on a high buildup of homeostatic sleep pressure). Older individuals (age >50) appear to be more at risk. While symptoms are transient, therapeutic approaches can alleviate or temper some of the side effects of travel by hastening synchronization of the internal and external circadian cycles. Behavioral treatments include appropriately timed bright-light exposure and avoidance of bright light during the nighttime in the new destination, while pharmacologic approaches include timed melatonin administration before bedtime both prior to and following travel, resulting in improved sleep quality and decreased night waking.

Social Jetlag Individuals with a late chronotype are prone to suffer from "social jetlag," a phenomenon in which individuals are forced to awaken at a point at which their bodies are entrained to be asleep due to discrepancy between alignment of social and biological time. Social jetlag can be estimated using questionnaires, such as the MCTQ, to compare sleep timing on nonfree compared with free days. This has established that a large proportion of the European population suffers from 2 or more hours of social jetlag. Chronic social jetlag is associated with an increased risk of developing obesity and the metabolic syndrome, as well as with greater alcohol consumption, smoking, and poorer academic performance in students.

The aforementioned categories of defined clinical circadian disorders have been traditionally established based on consideration of the endogenous behavioral and physiologic cycles (primarily of melatonin and temperature) with the external 24-h light-dark cycle. In the following sections, we build on the concepts of circadian behavioral disorders to consider new and emerging insight into the role of circadian disruption in organismal homeostasis **(Figs. 485-3 and 485-4)** and the availability of genetic strategies to dissect the interrelationship between clock function, health, and disease.

ROLE OF THE CLOCK SYSTEM IN PHYSIOLOGY

Endocrine Systems Regulated by the Circadian Clock In addition to regulation of behavioral rhythms such as sleep-wake and fasting-feeding cycles, the circadian clock also regulates rhythms of the endocrine system. Cortisol rhythms are regulated through a

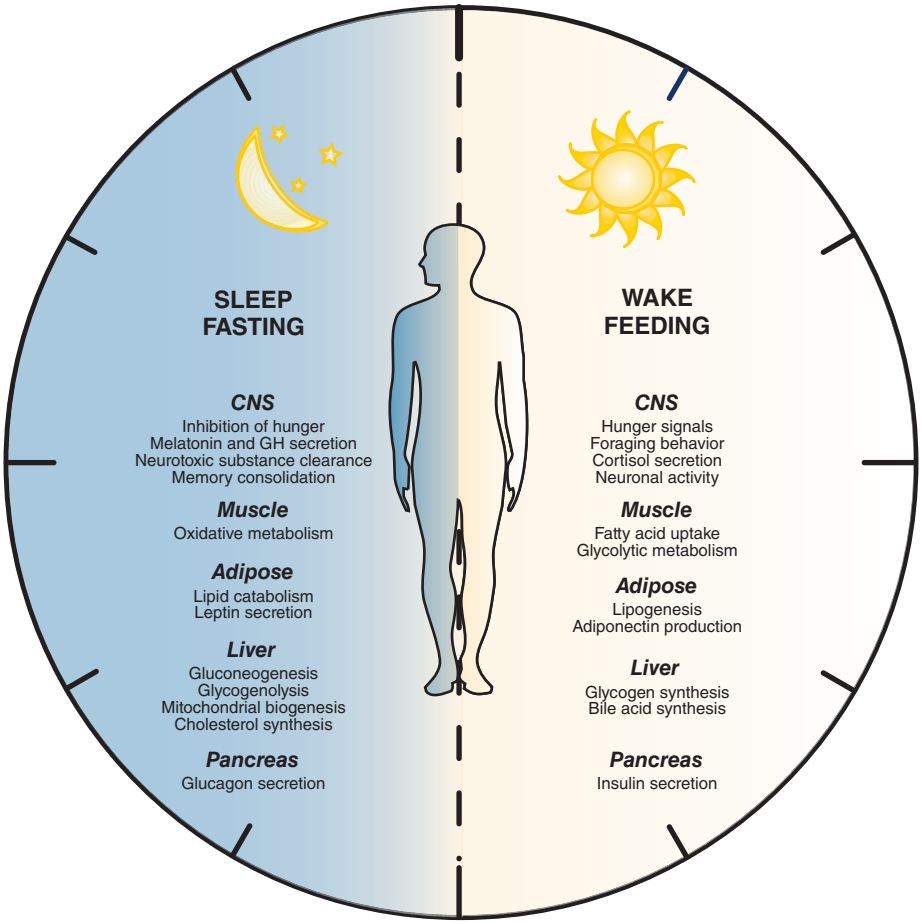

FIGURE 485-3 The circadian clock partitions behavioral, physiologic, and metabolic processes according to time of day. The partitioning of metabolic processes to appropriate times of day is critical for the maintenance of health from cellular to mammalian organisms. This figure highlights which processes peak within the central nervous system (CNS), muscle, adipose, liver, and pancreas during either the sleep/fasting or wake/feeding cycle in humans. GH, growth hormone.

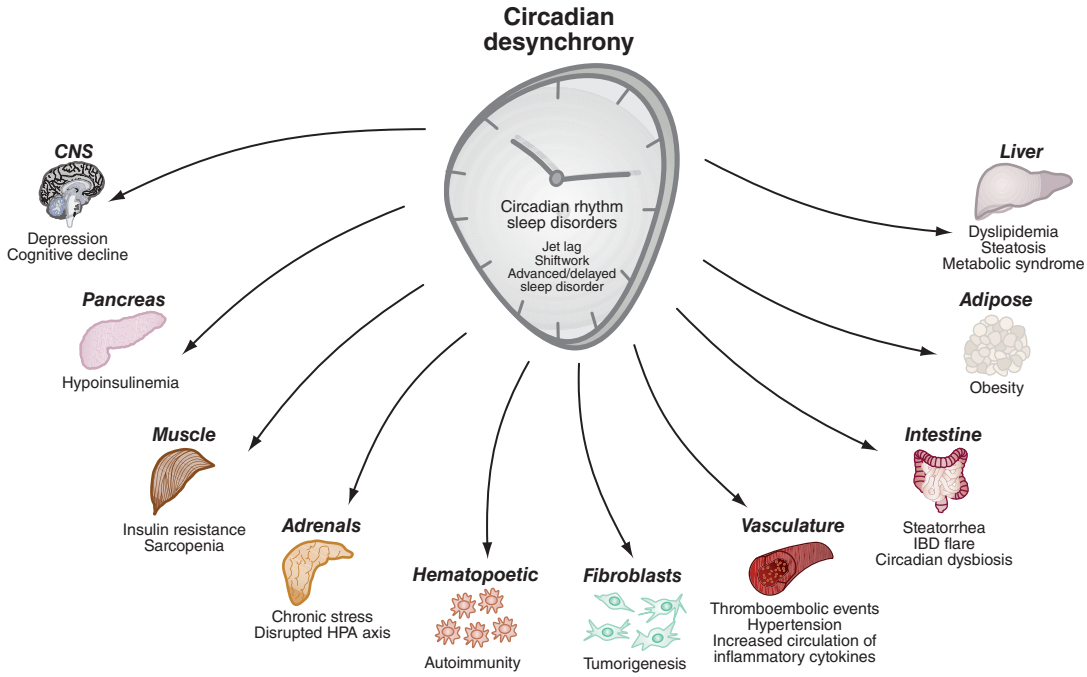

FIGURE 485-4 Pathologies resulting from circadian desynchrony. Circadian rhythm sleep disorders, including advanced/delayed sleep phase disorder, jet lag, social jet lag, and shift work, result in a desynchrony between the environmental light-dark cycle "time" and the endogenous clock "time." Pathologies can thus arise through misalignment imposed by exogenous (e.g., altered light cycle and/or feeding rhythm) and endogenous factors (e.g., mutations in core clock genes). Such desynchrony results in a host of wide-ranging pathologies across multiple tissues, including hypoinsulinemia (pancreas), disrupted hypothalamic-pituitary-adrenal (HPA) axis, autoimmunity, hypertension, obesity, and metabolic syndrome. CNS, central nervous system; IBD, inflammatory bowel disease.

feedback loop known as the HPA axis. Hypothalamic secretion of CRH and AVP promotes secretion of pituitary ACTH, which in turn regulates rhythmic cortisol secretion from the adrenal cortex. Cortisol release increases toward the morning, and this increase is believed to prepare the brain and peripheral tissues for daytime activity and food intake. AVP secretion in mice occurs prior to sleep to promote water intake, thereby preventing dehydration during the sleep period. Several hormonal systems are in fact influenced more by sleep than by circadian rhythms. For instance, secretion of growth hormone (GH) is profoundly blunted during acute overnight wakefulness. The secretion of this hormone is primarily dependent on the occurrence of slow-wave sleep, which is a homeostatically driven sleep stage that occurs primarily in the first part of the sleep period. Cortisol also exhibits a peak close after wakefulness: the cortisol awakening response (CAR). This peak seems to be independent of a circadian rhythm, as the CAR is severely blunted by acute overnight wakefulness, and both the CAR and daytime cortisol are modulated by light exposure levels. Curtailed sleep and overnight wakefulness increase the activity of the HPA axis and may increase diurnal cortisol levels. Sleep also influences melatonin amplitude, such that sleep deprivation can increase melatonin levels.

In working environments, the effects of curtailed sleep are often confounded by mistimed exposure to light. Even low levels of light are able to potently suppress melatonin secretion. Together with altered timing in light exposure, perturbed hormonal levels likely represent a mechanism through which altered timing and duration of sleep can impact central and peripheral circadian oscillators.

Centrally-controlled rhythms of melatonin and cortisol are considered key regulators of extra-SCN and peripheral oscillators. Glucocorticoid receptors exist in both the central nervous system and in peripheral tissues such as skeletal muscle, liver, and adipose tissue. Upon acute shifts in light-dark or feeding cycles, rhythmic levels in cortisol appear to modulate the rate at which behavioral and physiological rhythms are able to phase shift. Indeed, glucocorticoids regulate clock gene expression in muscle, kidney, and lung, while the powerful synthetic glucocorticoid dexamethasone is often employed in vitro for its property to synchronize (e.g., reset) circadian rhythms of cells, including liver cells. Consistent with a role for glucocorticoid regulation of the clock, both adrenalectomy, which results in a lack of cortisol, and exogenous corticosteroid supplementation significantly disrupt the circadian clock system.

Several peripherally-produced hormones and peptides are not only produced rhythmically but can also feed back to central clocks, including the SCN. For instance, both cortisol and thyroid hormones regulate their own rhythmic synthesis by feedback to central brain regions, i.e., the hypothalamus (for cortisol) and pituitary (for both hormones). Several other peripherally-produced factors have been proposed to influence the central clock, including fatty acids produced by the adipose tissue and fibroblast growth factor 21, a hormone primarily produced by the liver. Peripheral hormones that signal energy state and hunger also exhibit circadian rhythms that seem to be regulated by local tissue clocks. The most extensively studied hormones are leptin, which is released from white adipose tissue cells, and ghrelin, which is released from specific endocrine cells in the upper fundus region of the stomach. Ghrelin also exhibits significant peaks related to anticipated meal timing, which persist for several days of fasting in humans. Circulating rhythms of leptin and ghrelin are disrupted in circadian mutant mice and are also perturbed in humans subjected to circadian misalignment, with evidence for sex-specific effects. For instance, *Per* and *Cry* mutant mice exhibit severely blunted leptin rhythms, and wild-type mice exposed to jetlag (through repeatedly altered light-dark cycles) show a reduced wake-associated decrease in leptin. Similarly, humans forced to live 28-h days exhibit increased 24-h profiles of ghrelin and conversely decreased levels of leptin. Ghrelin and leptin signal to several regions of the brain, including integrative appetitive regions of the hypothalamus such as the arcuate and paraventricular region. The response to these hormones is rhythmically regulated by the molecular clock within several such central sites, effectively gating how these hormones influence rhythms of food intake and energy homeostasis in a time-of-day– and nutrient-dependent manner.

Role for the Clock in Metabolic Homeostasis Circadian control of glucose homeostasis has long been recognized, as early studies demonstrated variation in glucose tolerance and insulin action across the day. For example, due to a combination of circadian control of both peripheral insulin sensitivity and pancreatic β-cell insulin secretion, oral glucose tolerance is lower in the evening and afternoon compared with the morning. Another example is the "dawn phenomenon," whereby glucose levels peak prior to the onset of activity. Further, destruction of the SCN has been shown to abolish circadian regulation of glucose metabolism in rats, and daily cycles of insulin secretion and glucose tolerance are often perturbed in patients with type 2 diabetes, who also exhibit changes in gene expression rhythms in peripheral tissues such as adipose tissue. Changes in rhythmic parameters such as insulin secretion have also been observed in first-degree relatives of patients with type 2 diabetes, possibly highlighting a key hereditary role for the circadian clock in the pathogenesis of metabolic disease.

Ablating clock genes in mice has revealed a key function for both central and peripheral clocks in regulating energy homeostasis. The circadian system has been shown to regulate rhythmic insulin secretion from the pancreas via both neural signals and hormonal levels (e.g., cortisol and norepinephrine), as well as via cell-autonomous clock regulation within the pancreatic β cell itself. An early observation was that whole-body *Clock*$^{\Delta 19/\Delta 19}$ mutant mice developed obesity without displaying hyperinsulinemia, a phenomenon that indicated concurrent β-cell failure. This was later confirmed using pancreas- and β-cell–specific *Bmal1*-deficient mice, which exhibited glucose intolerance, hypoinsulinemia, and impaired glucose-stimulated insulin secretion. The molecular clock within other peripheral tissues such as liver, adipose tissue, and skeletal muscle also regulates circadian fluctuations in insulin sensitivity and glucose disposal, which are highest in the morning and decline toward the evening. Liver-specific *Bmal1* mutant studies have revealed liver clock promotion of gluconeogenesis, glycogenolysis, and mitochondrial oxidative metabolism in the sleep/fasting period while promoting glycogen synthesis in the wake/feeding period. Muscle-specific *Bmal1*-deficient mice display reduced glucose tolerance, concomitant with lower levels of proteins involved in glucose uptake by muscle cells (e.g., the glucose transporter GLUT4). Ablation of the *Cry1* and *Cry2* repressors in the negative limb of the clock alters glucagon and glucocorticoid signaling in the liver, contributing to hyperglycemia and impaired glucose tolerance in these mutant mice. Together, these genetic studies in mice suggest a role for tissue-specific clocks in the partitioning of energy utilization across the sleep-wake cycle.

Importantly, peripheral clocks also interact with other environmental factors such as diet and time of feeding. For example, high-fat feeding leads not only to obesity and metabolic syndrome in mice, but also to perturbed clock gene expression across multiple peripheral tissues and a disrupted sleep-wake/fasting-feeding cycle, as revealed by increased activity and feeding during the daytime. Furthermore, mice that are fed a high-fat diet exclusively during their (inactive) light phase gain significantly more weight than mice that are fed the same diet during the dark period—the active period for mice. Additionally, the metabolic phenotypes arising from ad lib high-fat feeding can be significantly ameliorated by restricting the time of high-fat feeding exclusively to the dark period. Animals with disrupted clock throughout the hypothalamus and SCN exhibit mistimed eating and adverse metabolic rhythms that can be restored by dark-only feeding. Time-restricted feeding can also increase the activity of brown adipose tissue in mice and reduce hepatic glucose production to instead promote beta oxidation of fatty acids. The potential clinical utility of time-restricted feeding has been corroborated in human interventional studies. These have demonstrated that dietary interventions modulate transcriptional rhythms across tissues and that time-restricted feeding can improve metabolic homeostasis as well as promote weight loss. Time-restricted feeding may also modulate central regulation of sleep and hunger, as studies have found that humans who restrict their food intake to a

shorter than ad lib period also consume fewer daily calories and report both lower hunger and improved sleep.

Finally, animal studies have further shown that when the light-dark cycle is disrupted or animals are subjected to conditions mimicking "jetlag"—by artificially advancing or delaying the daily light period—there is desynchronization among circadian clocks and subsequent weight gain. Accumulating evidence in humans also finds that circadian misalignment both disrupts and desynchronizes circadian clocks across tissues. Clinical studies that have sampled tissues such as blood, skeletal muscle, and adipose tissue at regular intervals have observed day-night rhythms in clock genes and metabolic genes and disruption of oscillating genes by sleep-wake interventions. Prolonged circadian misalignment using forced desynchrony protocols reduces insulin sensitivity in the pre- and post-prandial state. Under such conditions, insulin secretion fails to suppress glucose levels, suggesting inadequate β-cell compensation. Moreover, resting metabolic rate declines significantly both in the awake and sleeping state, altogether providing potential explanations why shift work can increase the risk of obesity, type 2 diabetes, and the metabolic syndrome.

Human genetic association studies also support a role for clock genes in metabolic homeostasis and β-cell function. Carriers of a certain *BMAL1* polymorphism have a greater risk of developing type 2 diabetes, while *CLOCK* variants have been found to interact with diet, such that variants can have a protective effect on insulin sensitivity in individuals with high monounsaturated fat intake or in individuals provided a low-fat diet. Instead, the minor allele of another *CLOCK* gene variant has been associated with increased waist circumference, but only in those with high saturated fat intake. Similarly, *NPAS2* and *BMAL1* variants have been associated with a greater risk of hypertension. Melatonin receptor *MTNR1B* gene variants that result in increased expression of MTNR1B have been associated with elevated fasting blood glucose levels and reduced insulin secretion irrespective of their level of glycemic control, consistent with the known effect of melatonin on insulin secretion and lower insulin secretion in the evening. These association studies highlight the role of the circadian system in metabolism, as well as the potential for interactions of external perturbations—such as circadian misalignment—with a protective or adverse genetic profile.

A large proportion of society recurrently shifts sleep-wake and eating times between working/nonfree days and free days. This social jetlag has been increasingly tied to metabolic disruptions, including a greater risk of obesity and type 2 diabetes. As this involves recurrent phase advances and phase delays—like shift work but of smaller magnitude—it is possible that social jetlag, and often interlinked eating jetlag, also results in perturbed rhythms of energy expenditure, in combination with disruptions to the circadian hunger drive, further increasing the risk of obesity. Repeated shifts in the food- and SCN-driven rhythm of insulin release may similarly over time increase the risk of type 2 diabetes. Shifted feeding rhythms in relation to the sleep-wake cycle and the timing of SCN activity may be causally involved in this pathogenesis. This is exemplified by the disorders known as night-eating syndrome and sleep-related eating disorder. In the former syndrome, a large part of daily calorie consumption occurs in the evening and nighttime hours, and this shifted meal pattern has been associated with a delayed timing of the internal clock. Some evidence exists that these syndromes are associated with obesity. Individuals who report sleeping fewer hours or who are subjected to restricted sleep for a few consecutive days have also been found to consume more calories, especially later in the evening, a period during which prolonged fasting favors oxidative fuel utilization. As such, this may explain why sleep restriction increases the risk of obesity. These associations have also been observed in individuals with later onset of sleep, i.e., evening chronotypes. Night-eating syndrome and later chronotypes have also been linked to type 2 diabetes and may be more common than other eating disorders such as binge-eating disorder. Both conditions have also been found to be associated with impaired glycemic control—such as a greater likelihood of hemoglobin A_{1c} values exceeding 7%—in patients already suffering from type 2 diabetes. This emphasizes how proper alignment of internal circadian rhythms with external factors are key contributing factors for long-term metabolic homeostasis.

Molecular circadian clocks are present not only within the extra-SCN regions of the brain but also in neurons, astrocytes, microglia, and cells of the blood-brain barrier. Emphasizing the functional significance of properly aligned clocks for brain health, shift workers have been found to have decreased gray matter in brain regions involved in memory and executive functions, with more notable effects in individuals who had shorter recovery periods between the onset of each shift work cycle. Adults performing rotating shift work for many years have also been shown to exhibit signs of accelerated cognitive aging. Notably, evidence suggests that these effects may be reversible, as those who have stopped carrying out shift work exhibit normal cognitive performance 5 or more years later.

Studies have also uncovered an important role for perturbed circadian and sleep-wake rhythms in neurodegenerative conditions such as Alzheimer's disease (AD), Huntington's disease (HD), and Parkinson's disease (PD). Amyloid beta (Aβ), a key pathognomonic component of AD, normally exhibits circadian fluctuations in the extracellular space in the brain, as well as in the cerebrospinal fluid and plasma in humans, peaking during the active period and falling during sleep. Of note, these daily rhythms of Aβ accumulation are dampened in mice that are prone to develop AD; reduced plasma Aβ fluctuations have also been noted in older compared with younger individuals. Animal studies indicate that removal of Aβ (and other neurotoxic substances) during the nighttime sleep period is facilitated by a lymphatic-like system that relies on glial cells (the "glymphatic" system). Relevance of this system to humans is suggested by the observation that slow-wave sleep is accompanied by hemodynamic fluctuations that alter the flow of cerebrospinal fluid, which can remove toxins such as Aβ. Consistent with a role for circadian rhythms in the pathogenesis of AD, ablation of core clock genes throughout the brain, within subregions of the brain or within glia, leads to pathology such as oxidative stress, neuronal cell death, and scarring of brain tissue (astrogliosis). Furthermore, perturbed light-dark cycles increased pathology associated with oxidative stress, and single nucleotide polymorphisms in *Clock* and *Bmal1* have been associated with increased risk of developing AD.

Evidence also indicates that the relationship between the circadian/sleep-wake system and AD is bidirectional. For example, patients suffering from AD exhibit several signs of perturbed circadian rhythms, the most prominent of such phenomena being "sundowning," whereby AD patients become more agitated and exhibit delirium-like symptoms in the afternoon or evening. Studies have furthermore indicated that in severe forms of AD, the circadian rhythm is phase delayed. Aged AD-prone mice also display perturbed sleep-wake patterns, which can be corrected by immunization against Aβ or by an orexin antagonist. Further research will help uncover the primary pathogenic contribution of the circadian system, and its independent contribution from perturbed sleep, in conditions like AD. Notably, evidence suggests that interventions that increase daytime light exposure and include melatonin supplementation are able to ameliorate symptoms of AD, presumably by counteracting disrupted circadian rhythms.

While the relation between shift work and depression has not been extensively studied, disruption of sleep and circadian rhythms and the pathogenesis of depression are intimately interlocked. Clock genes have also been implicated in depression and mood both in animal and human studies. Polymorphisms of genes that regulate sleep and circadian rhythms—for instance, a long gene variant of *PER3*—have also been linked to bipolar disorder and schizophrenia, while *CRY2* and *CLOCK* gene polymorphisms are associated with seasonal affective disorder, a type of depression arising in the fall and winter months when the levels of sunlight are lowest. Bipolar disorder is furthermore often triggered by circadian disruptions or curtailed sleep. Both bipolar disorder and schizophrenia have been linked to various forms of circadian disruption following disease onset, and a critical component of disease treatment often involves normalizing sleep and sleep-wake rhythms.

Sleep deprivation by itself is known to reduce alertness, impair decision-making, and increase risk for accidents—after 18–24 h of continuous wakefulness, several skills exhibit the same degree of decline as following mild alcohol intoxication. However, cognitive abilities may

suffer even further when sleep restriction is combined with circadian misalignment as in shift work. In one study, participants were subjected to ~43-h long days in parallel with reduced sleep (equivalent to 5.6 h of sleep in a 24-h period), yielding a forced desynchrony protocol coupled with sleep loss. When subjects were tested at the nadir of their circadian period, the subjects' reaction speed dropped almost by an order of magnitude compared with controls. In another study, researchers noted almost a 36% greater incidence of serious medical errors in resident interns who regularly worked 24-h or longer shifts compared with those who were randomly assigned to work up to 16-h-long shifts. Furthermore, errors that resulted in patient death were three times more likely to occur in residents working extended hours compared with those who only worked up to 16-h-long shifts.

Circadian Regulation of Gastrointestinal Homeostasis and the Microbiota Physiologic aspects of the gastrointestinal (GI) tract exhibit day-night variations that anticipate and prepare for food intake and digestion during the active period. Gastric emptying and colonic motility are considerably greater during the active phase, as the phasic motor program supporting movement of digested material along the intestine is approximately twice as fast during the day compared with night. Bile acid secretion also exhibits circadian rhythmicity in the intestine, as does absorption and the expression of many nutrient uptake transporters in the intestinal wall, including the main glucose transporter protein SGLT1. The permeability of the intestinal wall also varies throughout the sleep-wake cycle, and mice exposed to chronic sleep fragmentation exhibit increased intestinal permeability, which may enable inflammatory molecules from bacteria to reach the systemic circulation.

The composition and function of the microbe population residing in the intestine (i.e., the gut microbiota) also display circadian rhythmicity, orchestrated by both host circadian clock gene expression and food intake rhythms. Accordingly, circadian disruption, either by environmental or genetic means, perturbs these microbial rhythms, disrupting both bacterial levels and the metabolic functions of the gut microbiota. For example, alterations in the expression and functions of the gut microbiota have been noted in humans exposed to acute jetlag, and evidence suggests that curtailing sleep, which often accompanies shift work and jetlag, can alter the gut microbiota. By increasing local and systemic inflammation, circadian disruption of the gut microbiota may be causally involved in the increased risk of inflammatory bowel disease (Crohn's disease and ulcerative colitis) and colon cancer in shift workers. Biological sex differences have also been reported, as female mice display more pronounced microbial rhythms. Interestingly, the gut microbiome has also been shown to influence the rhythms of host tissues, such as the intestine and liver, that also appear sex-specific. This indicates that a bidirectional relationship exists between tissues that regulate metabolic processes and the gut microbiome across the sleep-wake cycle. These findings may furthermore have clinical implications, given that the gut microbiome may both directly (in the gut lumen) and indirectly (through host-microbiota interactions such as through signaling molecules) impact metabolic responses and pharmacokinetic and pharmacodynamic properties of therapeutic drugs across the 24-h day-night cycle.

Cardiovascular Health and the Circadian Clock An early epidemiologic observation was a greater incidence of myocardial infarction in the morning hours, with the lowest risk during the period preceding sleep. Other cardiovascular outcomes such as sudden cardiac death and syncope also exhibit a daily peak in the morning. Blood pressure (BP) typically peaks around 2100 h and decreases later during sleep, partially due to a circadian nighttime dip of around 3–6 mmHg in systolic BP and 2–3 mmHg in diastolic BP. A dip in BP of either <10% or >20% during normal sleep has been associated with worse cardiovascular prognosis and risk of dementia. Heart rate also typically decreases during sleep, while mistimed sleep leads to higher heart rate during sleep time. Studies also suggests that heart muscle may be more tolerant to hypoxia and thus fare better under surgery scheduled for the afternoon, due to timing of cellular programs driven by the cell autonomous clock in cardiomyocytes. Thus, a combination of factors—which may also involve altered glucocorticoid levels and increased platelet aggregation—may contribute to a greater risk of cardiovascular disease in the morning. Subsequent epidemiologic studies also have demonstrated that shift work increases the risk of dyslipidemia and hypertension, as well as the risk of coronary heart disease, including myocardial infarction. These findings are in line with interventional findings in which circadian misalignment has been induced either by inverting the sleep-wake cycle or by imposing 28-h days on healthy human subjects. These studies have found that circadian misalignment elevates 24-h BP, particularly during sleep. These changes may be causally related to how the autonomic system is regulated during sleep, as evidenced by reduced vagal cardiac control when the sleep-wake cycle is inverted.

Circadian Disruption and Cancer In 2007, the International Agency for Research on Cancer declared that shift work that involves circadian disruption is likely carcinogenic to humans. While evidence for an association between shift work and general cancer incidence is mixed, accruing evidence supports a link between shift work and increased risk of developing colon and breast cancer, as well as having a poorer cancer prognosis. Telomere shortening, a phenomenon in aging that destabilizes the genome, has also been observed in shift workers as well as in individuals suffering from short sleep. Such changes may reduce the ability of damaged or senescent cells to undergo apoptosis and, instead, lead to uninhibited cell growth and cancer. An indirect role for the circadian clock has also come from retrospective studies on how cancer risk is related to food timing and duration of the nighttime fast in humans. In combination with interventional time-restricted studies, these indicate that by portioning food intake to a restricted period of the day, optimized portioning of circadian processes confers a reduced risk of potentially carcinogenic cell damage. Studies of recurring fasting have also shown that it lowers the risk and delays the onset of cancer.

Experimental genetic evidence has also implicated clock disruption as a factor in tumorigenesis. Genetic loss of *Per2* or *Bmal1* has been shown to promote lung tumorigenesis, while studies in *Per2* mutant mice have also revealed increased radiation-induced lymphoma associated with dysregulation of the cell cycle. However, disruption of the *Cry* gene in mice has also been implicated in tumor protection due to increased susceptibility to cell death. In contrast, pharmacologic overactivation of REV-ERB may impair growth of glioblastomas. While epidemiologic, experimental, and chronotherapeutic evidence (see section "Chronotherapy and Future Directions") suggests a link between circadian disruption and cancer, the precise role of circadian systems in tumorigenesis remains to be determined.

Circadian Regulation of the Immune System Circadian misalignment and sleep restriction both alter population levels of immune cells and decrease the ability of immune cells to produce reactive radicals, in part likely through disruption of cytokine rhythms. Chronic circadian disruption may thereby impair the immune system's ability to conduct immunosurveillance at the proper time of day. This may reduce the ability to mount an appropriate pathogen-induced effector (cytotoxic T-cell) response during the active period, as well as impair the more long-term adaptive immune response, which is favored by the cytokine milieu (such as surges in prolactin and GH) that accompanies the recovery/sleep phase. Instead, circadian misalignment increases a range of clinically-used inflammatory markers (e.g., C-reactive protein, tumor necrosis factor α, and interleukin 6), and such changes have been noted even when the sleep-wake cycle is only prolonged to a slightly longer than normal 24.6-h day. While similar effects are also observed following acute total sleep deprivation or recurrent partial sleep restriction, circadian misalignment has been found to promote an even more pronounced elevation of such markers. Genetic clock disruption in peritoneal macrophages has also revealed clock control of Toll-like receptor 9, which is responsible for identifying molecules from foreign pathogens. Clock knockout mice also have reduced T-cell antigen response, and mice immunized during the day had a stronger T-cell response than mice immunized at night, supporting regulation of the immune system by the clock. Similar mechanisms likely take place in humans, as clinical studies have noted an impaired vaccine

response following sleep disruption, and several studies have noted an improved immunogenic response to various antigens when vaccinated in the morning compared with afternoon.

Aging and the Circadian Clock Instability in the clock system is an often-overlooked hallmark of aging. Aging is associated with a decline in the robustness of intrinsic rhythmic processes at the behavioral, physiologic, and molecular levels in both human and animal models. At the behavioral level, aging leads to reduced and fragmented sleep, dampened locomotor activity and feeding rhythms, and a reduced ability to entrain to light, as old rodents are 20 times less sensitive to the entraining effects of light relative to young animals. Even middle-aged individuals exposed to jetlag exhibit more symptoms of circadian misalignment, such as more time awake and reduced alertness, compared with young individuals. On a physiologic level, some of the hallmarks of aging are a reduction in amplitude (e.g., flattening of circadian pattern) that also impacts the signal during the evening period (the wake maintenance zone). Aging also results in a phase advance (e.g., a shift in the timing of the peak or nadir) in rhythms of the endocrine and neuroendocrine systems, including sleep onset and offset. For example, cortisol, dehydroepiandrosterone (DHEA), and melatonin all have dampened rhythms and are phase advanced in aging; the combination of such changes may, for instance, contribute to more fragmented sleep and lower levels of restorative slow-wave sleep in aged individuals. Relatedly, aging results in reduced peptide expression in the SCN (VIP and AVP), cell loss in sleep-wake regions (including the SCN), and reduced amplitude of rhythms of SCN electrical activity. Further, while the SCN-dependent body temperature rhythm—a generally accepted marker for the integrity of circadian rhythms—peaks in the evening and is lowest in the early morning in young individuals, aged healthy subjects display a phase advance and decrease in circadian amplitude in body temperature rhythms. Indeed, evidence suggests that internal desynchrony between core body temperature rhythms and the sleep-wake cycle may contribute to age-associated circadian alterations.

On a molecular level, aging is associated with decreased expression and altered diurnal profiles of several of the core clock genes, including *Clock* and *Bmal1*, within both SCN and peripheral tissues such as heart and liver. The acute induction of *Per1* in response to light was markedly reduced in the SCN of aged mice compared with young mice, potentially contributing to their delayed response to light entrainment. Mice lacking *Bmal1* die prematurely compared with control mice, consistent with premature accumulation of reactive oxygen species. These mice have an accelerated onset of numerous age-related pathologies, including cataracts, sarcopenia, reduced organ size, and decreased hair growth. Instead, deficiency of cryptochrome, a repressor of the internal clock repressor, has been associated with alterations in liver regeneration, while *BMAL1* and *PER2* may be important for proper neurogenesis in the hippocampus, a brain region in which adult mammals normally exhibit continuous cell division. Altogether, this suggests that the highly conserved circadian clock is important for regulating a wide range of homeostatic processes, including cell-cycle pathways, which when properly phased to each other promote organismal fitness.

Measurements of altered circadian rhythms with age may serve as a useful biomarker for aging. An intriguing question is whether the decline in amplitude of rhythms correlates with a decline in function and, importantly, whether restoration of these rhythms with age, through either behavioral or pharmacologic intervention, would delay the aging process. Studies in mice indicate that behavioral and pharmacologic interventions (including exercise) can restore circadian oscillations in aging. Similarly, transplantation of the SCN from a young rat into an old rat "rescued" the rhythms of both locomotor activity and corticotropin hormone (CRH), suggesting that the SCN is an important target for age-related changes in clocks. Physical activity or targeted therapeutics may therefore ameliorate some of the circadian deterioration in aged humans.

CHRONOTHERAPY AND FUTURE DIRECTIONS

Chronopharmacology, the study of how the timing of drug administration may impact its effectiveness, is a rapidly emerging field. Since physiologic processes vary across the day, the timing of administration of medication may help optimize patient care. For example, since endogenous cholesterol synthesis is rhythmic in liver and peaks during the early morning hours, administration of statins (HMG-CoA reductase inhibitors) in the evening prior to bedtime has proven to be more effective than daytime administration at reducing low-density lipoprotein cholesterol (LDL-C) levels because the highest concentration of medication coincides with the peak in rhythmic endogenous cholesterol production. Given that BP exhibits a 24-h rhythm—being lowest during sleep—angiotensin-converting enzyme (ACE) inhibitors have been shown to be most effective at night to normalize the BP rhythms, restoring the nighttime dip in BP that is foremost tied to the occurrence of sleep. Numerous studies have also demonstrated that administration of cancer treatments at specific times of the day can increase chemotherapy effectiveness while also decreasing toxicity for a wide range of drugs. For example, 5-fluorouracil works best to treat colorectal cancer when administered at night, a time when the cancerous cells are more vulnerable while normal cells are quiescent and therefore less sensitive. Doxorubicin administration early in the morning to treat ovarian cancer has also been shown to be less toxic, as white blood cells recover faster than if the drug is given in the evening. Finally, the more severe morning symptoms of rheumatoid arthritis are linked to increased inflammation toward the evening; therefore, prevention of the nighttime upregulation of the immune/inflammatory reaction is more effective when glucocorticoids are administered with a nighttime release formulation.

Recognition of circadian rhythms is also critical for diagnoses and treatment of endocrine disorders. The diagnosis of Cushing's syndrome, which is characterized by hypercortisolemia, might be missed if the patient's cortisol levels are measured in the morning, when endogenous cortisol production peaks. Therefore, clinical diagnosis requires cortisol to be measured in the late evening when the levels of this hormone should typically be low. On the other hand, adrenal insufficiency is diagnosed by measuring cortisol in the morning when at its physiologic peak, and glucocorticoid therapy for these patients aims to mimic the endogenous rhythms of cortisol, as short-acting synthetic glucocorticoids are usually given several times a day in tapering doses, such that the largest amount is taken in the morning and the smallest in the evening. Diabetes is another endocrine disorder intimately tied to circadian rhythms. Oral glucose tolerance, which is commonly used to diagnose diabetes, is worse in the afternoon and evening compared with the morning. This likely stems from greater daytime insulin sensitivity within peripheral tissues and reduced insulin secretion during the night. Similarly, due to a surge in hormone levels in the morning, diabetes patients may suffer from the dawn phenomenon (or dawn effect), an abnormally high morning increase in blood glucose due to impaired response in insulin secretion. A related phenomenon that can be tied to evening timing of insulin doses is the "rebound" or Somogyi effect. In this scenario, the initially noted clinical sign in the form of elevated glucose levels may be noted in the morning. However, the underlying cause is hypoglycemia occurring during the night, which produces a counterregulatory hormonal response that subsequently results in morning hyperglycemia. As patients with type 2 diabetes often have grossly impaired daily cycles of insulin secretion and glucose tolerance, this further highlights that time of day is an important consideration for the diagnosis and treatment of metabolic disorders such as type 2 diabetes.

As our knowledge of the complexity of how circadian processes modulate physiology deepens, further advances to rationally develop new strategies for treatments of disorders affected by circadian misalignment are essential. For example, novel compounds have begun to emerge from unbiased drug discovery screens that in cell- and animal-based assays impact circadian clock components, either shortening or lengthening the period. These compounds include CRY stabilizers and various inhibitors of CKIδ, CKIε, and GSK-3. Pharmacologic control of the circadian cycle may be useful in the treatment of circadian disorders and metabolic disturbances with a circadian component. Understanding how the circadian clock controls biological functions will shed new light onto the pathogenesis of metabolic

 disorders with a circadian component, such as type 2 diabetes and metabolic syndrome, and will yield insight into how timing of drug delivery will impact patient care.

486 Network Medicine: Systems Biology in Health and Disease

Joseph Loscalzo

The field of human biology has progressed over the past three centuries largely as a result of the reductionist approach to the scientific problems that challenge the discipline. Biologists study the experimental response of a variable of interest in a cell or organism while holding all other variables constant. In this way, it is possible to dissect the individual components of a biologic system and assume that a thorough understanding of a specific component (e.g., an enzyme or a transcription factor) will provide sufficient insight to explain the global behavior of that system (e.g., a metabolic pathway or a gene network, respectively). Biologic systems are, however, much more complex than this approach assumes and manifest behaviors that frequently (if not invariably) cannot be predicted from knowledge of their component parts characterized in isolation. Growing recognition of this shortcoming of conventional biologic research has led to the development of a new discipline, *systems biology*, which is defined as the holistic study of living organisms or their cellular or molecular network components to predict their response to perturbations. Concepts of systems biology can be applied readily to human disease and therapy and define the field of *systems pathobiology*, in which genetic or environmental perturbations produce disease and drug perturbations restore normal system behavior.

Systems biology evolved from the field of systems engineering in which a linked collection of component parts constitutes a network whose output the engineer wishes to predict. The simple example of an electronic circuit can be used to illustrate some basic systems engineering concepts. All the individual elements of the circuit—resistors, capacitors, transistors—have well-defined properties that can be characterized precisely. However, they can be linked (wired or configured) in a variety of ways, each of which yields a circuit whose response to a voltage applied across it is different from the response of every other configuration. To predict the circuit's (i.e., system's) behavior, the engineer must study its response to perturbation (e.g., voltage applied across it) holistically rather than its individual components' responses to that perturbation. Viewed another way, the resulting behavior of the system is greater than (or different from) the simple sum of its parts, and systems engineering utilizes rigorous mathematical approaches to predict these complex, often nonlinear, responses. By analogy to biologic systems, one can reason that detailed knowledge of a single enzyme in a metabolic pathway or of a single transcription factor in a gene network will not provide sufficient detail in context to predict the output of that metabolic pathway or transcriptional network, respectively. Only a systems-based approach will suffice.

It has taken biologists a long time to appreciate the importance of systems approaches to biomedical problems. Reductionism has reigned supreme for many decades, largely because it is experimentally and analytically simpler than holism and because it has provided insights into biologic mechanisms and disease pathogenesis that have led to successful therapies. However, reductionism cannot solve all biomedical problems. For example, the so-called off-target effects of new drugs that frequently limit their adoption likely reflect the failure of a drug to be studied in holistic context, that is, the failure to explore all possible actions aside from the principal target action for which it was developed. Other approaches to understanding biology are, therefore, clearly needed. With the growing body of genomic, proteomic, and metabolomic data sets in which dynamic changes in the expression of many genes and many metabolites are recorded after a perturbation and with the growth of rigorous mathematical approaches to analyzing those changes, the stage has been set for applying systems engineering principles to modern biology.

Physiologists historically have had more of a (bio)engineering perspective on the conduct of their studies and have been among the first systems biologists. Yet, with few exceptions, they, too, have focused on comparatively simple physiologic systems that are tractable using conventional reductionist approaches. Efforts at integrative modeling of human physiologic systems, as first attempted by Guyton for blood pressure regulation, represent one application of systems engineering to human biology. These dynamic physiologic models often focus on the acute response of a measurable physiologic parameter to a system perturbation, and do so from a classic analytic perspective in which all the conventional physiologic determinants of the output parameter are known and can be modeled quantitatively.

Until recently, molecular systems analysis has been limited owing to inadequate knowledge of the molecular determinants of a biologic system of interest. Although biochemists have approached metabolic pathways from a systems perspective for >50 years, their efforts have been limited by the inadequacy of key information for each enzyme (K_M, k_{cat}, and concentration) and substrate (concentration) in the pathway. With increasingly rich molecular data sets available for systems-based analyses, including genomic, transcriptomic, proteomic, and metabolomic data, molecular biologists and biochemists are now poised to use systems biology approaches to explore biologic and pathobiologic phenomena.

PROPERTIES OF COMPLEX BIOLOGIC SYSTEMS

To understand how best to apply the principles of systems biology to human biomedicine, it is necessary to review briefly the building blocks of any biologic system and the determinants of system complexity. All systems can be analyzed by defining their static topology (architecture) and their dynamic (i.e., time-dependent) response to perturbation. In the discussion that follows, system properties are described that derive from the consequences of topology (form) or

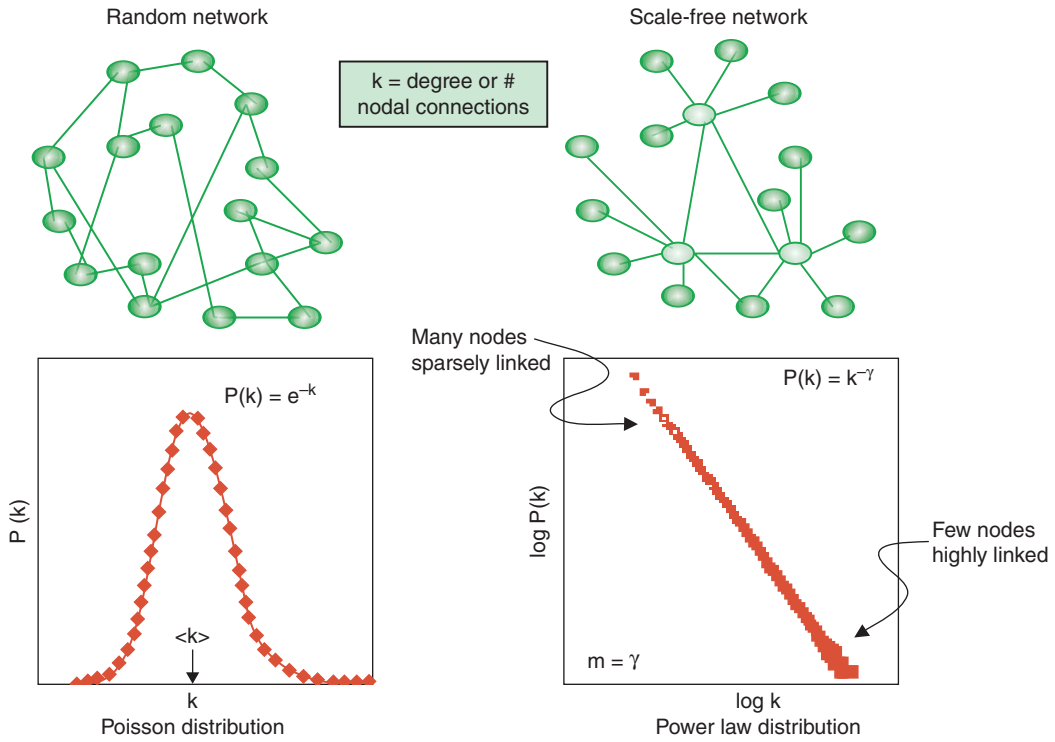

FIGURE 486-1 Network representations and their distributions. A random network is depicted on the left, and its Poisson distribution of the number of nodal connections (k) is shown in the graph below it. A scale-free network is depicted on the right, and its power law distribution of the number of nodal connections (k) is shown in the graph below it. Highly connected nodes (hubs) are lightly shaded.

dynamic response (function). Any system of interacting elements can be represented schematically as a *network* in which the individual elements are depicted as nodes and their connections are depicted as links. The nature of the links among nodes reflects the degree of complexity of the system. *Simple systems* are those in which the nodes are linearly linked with occasional feedback or feedforward loops modulating system throughput in highly predictable ways. By contrast, *complex systems* are nodes that are linked in more complicated, nonlinear networks; the behavior of these systems by definition is inherently more difficult to predict owing to the nature of the interacting links, the dependence of the system's behavior on its initial conditions, and the inability to measure the overall state of the system at any specific time with great precision. Complex systems can be depicted as a network of lower-complexity interacting components or modules, each of which can be reduced further to simpler analyzable canonical motifs (such as feedback and feedforward loops or negative and positive autoregulation); however, a central property of complex systems is that simplifying their structures by identifying and characterizing the individual nodes and links or even simpler substructures does not necessarily yield a predictable understanding of a system's behavior. Thus, the functioning system is greater than (or different from) the sum of its individual, tractable parts.

Defined in this way, most biologic systems are complex systems that can be represented as networks whose behaviors are not readily predictable from simple reductionist principles. The nodes, for example, can be metabolites that are linked by the enzymes that cause their transformations, transcription factors that are linked by the genes whose expression they influence, or proteins in an interaction network that are linked by cofactors that facilitate interactions or by thermodynamic forces that facilitate their physical association. Biologic systems typically are organized as *scale-free*, rather than stochastic, networks of nodes. Scale-free networks are those in which a few nodes have many links to other nodes (highly linked nodes, or hubs), but most nodes have only a few links (weakly linked nodes). The term *scale-free* refers to the fact that the connectivity of nodes in the network is invariant with respect to the size of the network. This is quite different from two other common network architectures: random (Poisson) and exponential distributions. Scale-free networks can be mathematically described by a power law that defines the probability of the number of links per node, $P(k) = k^{-\gamma}$, where k is the number of links per node and γ is the slope of the log P(k) versus log(k) plot; this unique property of most biologic networks is a reflection of their self-similarity or fractal nature **(Fig. 486-1)**.

There are unique properties of scale-free biologic systems that reflect their evolution and promote their adaptability and survival. Biologic networks likely evolved one node at a time in a process in which new nodes are more likely to link to a highly connected node than to a sparsely connected node. Furthermore, scale-free networks can become sparsely linked to one another, yielding more complex, *modular scale-free topologies*. This evolutionary growth of biologic networks has three important properties that affect system function and survival. First, this scale-free addition of new nodes promotes *system redundancy*, which minimizes the consequences of errors and accommodates adverse perturbations to the system robustly with minimal effects on critical functions (unless the highly connected nodes are the focus of the perturbation). Second, this resulting network redundancy provides a survival advantage to the system. In complex gene networks, for example, mutations or polymorphisms in weakly linked genes account for biodiversity and biologic variability without disrupting the critical functions of the system; only mutations in highly linked (*essential*) genes (hubs) can shut down the system and cause embryonic lethality. Third, scale-free biologic systems facilitate the flow of information (e.g., metabolite flux) across the system compared with randomly organized biologic systems; this so-called "small-world" property of the system (in which the clustered nature of the highly linked hubs defines a local neighborhood within the network that communicates through weaker, less frequent links to other clusters) minimizes the energy cost for the dynamic action of the system (e.g., minimizes the transition time between states in a metabolic network).

These basic organizing principles of complex biologic systems lead to three unique properties that require emphasis. First, biologic systems are *robust*, which means that they are quite stable in response to most changes in external conditions or internal modification. Second, a corollary to the property of robustness is that complex biologic

systems are *sloppy*, which means that they are insensitive to changes in external conditions or internal modification except under certain uncommon conditions (i.e., when a hub is involved in the change). Third, complex biologic systems exhibit *emergent properties*, which means that they manifest behaviors that cannot be predicted from the reductionist principles used to characterize their component parts. Examples of emergent behavior in biologic systems include spontaneous, self-sustained oscillations in glycolysis; spiral and scroll waves of depolarization in cardiac tissue that cause reentrant arrhythmias; and self-organizing patterns in biochemical systems governed by diffusion and chemical reaction.

APPLICATIONS OF SYSTEMS BIOLOGY TO PATHOBIOLOGY

The principles of systems biology have been applied to complex pathologic processes with growing successes. The key to these applications is the identification of emergent properties of the system under study in order to define novel, otherwise unpredictable (i.e., from the reductionist perspective) methods for regulating the system's response. Systems biology approaches have been used to characterize epidemics and ways to control them, taking advantage of the scale-free properties of the network of infected individuals that constitute the epidemic. Through the use of a systems analysis of a neural protein-protein interaction network, unique disease-modifying proteins have been identified that are common to a wide range of cerebellar neurodegenerative disorders causing inherited ataxias. Systems analysis and disease network construction of a pulmonary arterial hypertension network led to the identification of a unique disease module involving a pathway governed by microRNA 21 and, more recently, to a novel profibrotic pathway that promotes vascular disease progression. Systems biology models have been used to dissect the dynamics of the inflammatory response using oscillatory changes in the transcription factor nuclear factor (NF)-κB as the system output. Systems biology principles also have been used to predict the development of an idiotypy–anti-idiotypy antibody network, describe the dynamics of species growth in microbial biofilms, and analyze the innate immune response. In each of these examples, a systems (patho) biology approach provided insights into the behavior of these complex systems that could not have been recognized with conventional scientific reductionism.

A unique application of systems biology to biomedicine is in the area of drug development. Conventional drug development involves identifying a potential target protein and then designing or screening compounds to identify those that inhibit the function of that target. This reductionist analysis has identified many potential drug targets and drugs, yet only when a drug is tested in animal models or humans are the systems consequences of the drug's action revealed; not uncommonly, so-called off-target effects may become apparent and be sufficiently adverse for researchers to cease development of the agent. A good example of this problem is the unexpected outcomes of the vitamin B–based regimens for lowering homocysteine levels. In these trials, plasma homocysteine levels were reduced effectively; however, there was no effect of this reduction on clinical vascular endpoints. One explanation for this outcome is that one of the B vitamins in the regimen, folate, has a panoply of effects on cell proliferation and metabolism that probably offset its homocysteine-lowering benefits, promoting progressive atherosclerotic plaque growth and its consequences for clinical events. In addition to these types of unexpected outcomes exerted through pathways that were not considered *ab initio*, conventional approaches to drug development typically do not take into consideration the possibility of emergent behaviors of the organism or the metabolic pathway or the transcriptional network of interest that may be influenced by the drug. Thus, a systems-based analysis of potential drugs (drug-target network analysis) can benefit the development paradigm both by enhancing the likelihood that a compound of interest will not manifest unforeseen adverse effects and by promoting novel analytic methods for identifying unique control points or pathways in metabolic or genetic networks that would benefit from drug-based modulation, including drug combinations. In addition and importantly, unbiased knowledge about the systems behavior of a drug can lead to rational approaches to drug repurposing.

SYSTEMS PATHOBIOLOGY AND HUMAN DISEASE CLASSIFICATION: NETWORK MEDICINE

Perhaps most important, systems pathobiology can be used to revise and refine the definition of human disease. The classification of human disease used in this and all medical textbooks derives from the correlation between pathologic analysis and clinical syndromes that began in the nineteenth century. Although this approach has been very successful, serving as the basis for the development of many effective therapies, it has major shortcomings. Those shortcomings include a lack of sensitivity in defining preclinical disease, a primary focus on overtly manifest disease, failure to recognize different and potentially differentiable causes of common late-stage pathophenotypes, and a limited ability to incorporate the growing body of molecular and genetic determinants of pathophenotype into the conventional classification scheme.

Two examples will illustrate the weakness of simple correlation analyses grounded in the reductionist principle of simplification (Occam's razor) used to define human disease. Sickle cell anemia, the "classic" Mendelian disorder, is caused by a Val6Gln substitution in the β chain of hemoglobin. If conventional genetic teaching holds, this single mutation should lead to a single phenotype in patients who harbor it (genotype-phenotype correlation). This assumption is, however, false, as patients with sickle cell disease manifest a variety of pathophenotypes, including hemolytic anemia, stroke, acute chest syndrome, bony infarction, and painful crisis, as well as an overtly normal phenotype. The reasons for these different phenotypic presentations include the presence of disease-modifying genes or gene products (e.g., hemoglobin F, hemoglobin C, glucose-6-phosphate dehydrogenase), (stochastic) exposure to adverse environmental factors (e.g., hypoxia, dehydration), and the genetic and environmental determinants of common intermediate pathophenotypes or endophenotypes (i.e., variations in those generic pathologic mechanisms underlying all human disease—inflammation, thrombosis/hemorrhage, fibrosis, cell proliferation, apoptosis/necrosis, immune response).

A second example of note is familial pulmonary arterial hypertension. This disorder is associated with well over 100 different mutations in three members of the transforming growth factor β (TGF-β) superfamily alone—bone morphogenetic protein receptor-2 (BMPR-2), activin receptor-like kinase-1 (Alk-1), and endoglin—as well as nine other genes with high levels of evidence, and five genes with lower levels of evidence. All of these different genotypes are associated with a common pathophenotype, and each leads to that pathophenotype by molecular mechanisms that range from haploinsufficiency to dominant negative effects. As only approximately one-fourth of individuals in families that harbor these mutations manifest the pathophenotype, other disease-modifying genes (e.g., the serotonin receptor 5-HT2B, the serotonin transporter 5-HTT), genomic and environmental determinants of common intermediate pathophenotypes, and environmental exposures (e.g., hypoxia, infective agents [HIV], anorexigens) probably account for the incomplete penetrance of the disorder.

On the basis of these and many other related examples, one can approach human disease from a systems pathobiology perspective in which each "disease" can be depicted as a network that includes the following modules: the primary disease-determining elements of the genome (or proteome, if posttranslationally modified), the disease-modifying elements of the genome or proteome, environmental determinants, and genomic and environmental determinants of the generic intermediate pathophenotypes. **Figure 486-2** graphically depicts these genotype-phenotype relationships as modules for the six common disease types with specific examples for each type. **Figure 486-3** shows a network-based depiction of sickle cell disease using this type of modular approach.

Goh and colleagues developed the concept of a human disease network **(Fig. 486-4)** in which they used a systems approach to

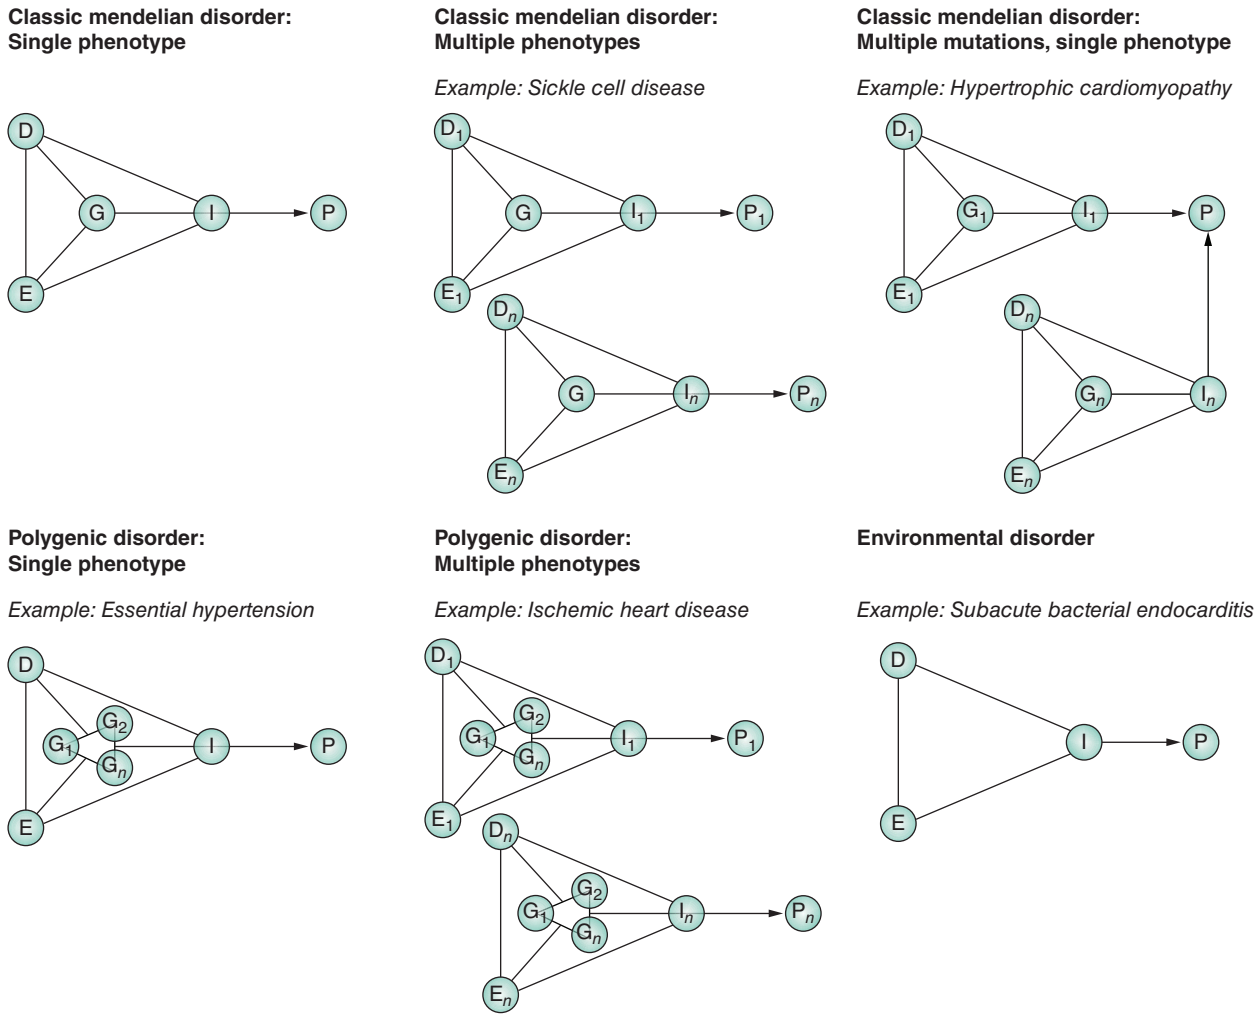

FIGURE 486-2 Examples of modular representations of human disease. D, secondary human disease genome or proteome; E, environmental determinants; G, primary human disease genome or proteome; I, intermediate phenotype; P, pathophenotype. *(Reproduced with permission from J Loscalzo et al: Human disease classification in the postgenomic era: A complex systems approach to human pathobiology. Molec Syst Biol 3:124, 2007.)*

characterize the disease-gene associations listed in the Online Mendelian Inheritance in Man database. Their analysis showed that genes linked to similar disorders are more likely to have products that physically associate and greater similarity between their transcription profiles than do genes not associated with similar disorders. In addition, proteins associated with the same pathophenotype are significantly more likely to interact with one another than with other proteins not associated with the pathophenotype. Finally, these authors showed that the great majority of disease-associated genes are not highly connected genes (i.e., not hubs) and are typically weakly linked nodes within the functional periphery of the network in which they operate. This set of observations led to a rigorous analysis by Menche and colleagues of 299 diseases whose associated proteins were found to cluster in discrete subnetworks or disease molecules within the global protein interaction network.

This type of analysis validates the potential importance of defining disease on the basis of its systems pathobiologic determinants. Clearly, doing so will require a more careful dissection of the molecular elements in the relevant pathways (i.e., more precise molecular pathophenotyping), less reliance on overt (common) manifestations of disease for their classification, and an understanding of the dynamics (not just the static architecture) of the pathobiologic networks that underlie pathophenotypes defined in this way. **Figure 486-5** illustrates the elements of a molecular network within which a disease module is contained. This network is first identified by determining the interactions (physical or regulatory) among the proteins or genes that comprise it (the "interactome"). These interactions then define a topologic module within which exist functional modules (pathways) and disease modules. One approach to constructing this module is illustrated in **Fig. 486-6**. Examples of the use of this approach in defining novel determinants of disease are given in **Table 486-1**.

Principles of network and systems biology can also be applied to clinical phenotyping. Rather than continuing to approach disease from an inclusive perspective, precision systems analysis of the molecular basis for disease must be linked to nuanced, deep phenotyping. This strategy will lead to the identification of subgroups of patients with a disease, each of which can be studied for differences in their disease modules that account for their phenotypic differences.

As yet another potential consideration, one can argue that disease reflects the later-stage consequences of the predilection of an organ system to manifest a particular intermediate pathophenotype in response to injury. This paradigm reflects a reverse causality view in which a disease is defined as a tendency to heightened inflammation, thrombosis, or fibrosis after an injurious perturbation. Where the process is manifest (i.e., the organ in which it occurs) is less important than that it occurs (with the exception of the organ-specific pathophysiologic consequences that may require acute attention). For example, from this perspective, acute myocardial infarction (AMI) and its consequences are a reflection of thrombosis (in the coronary artery), inflammation (in the acutely injured myocardium), and fibrosis (at the site or sites of cardiomyocyte death). In effect, the major therapies for AMI address these intermediate pathophenotypes (e.g., antithrombotics, statins) rather than any organ-specific disease-determining process. This paradigm would argue for a systems-based analysis that

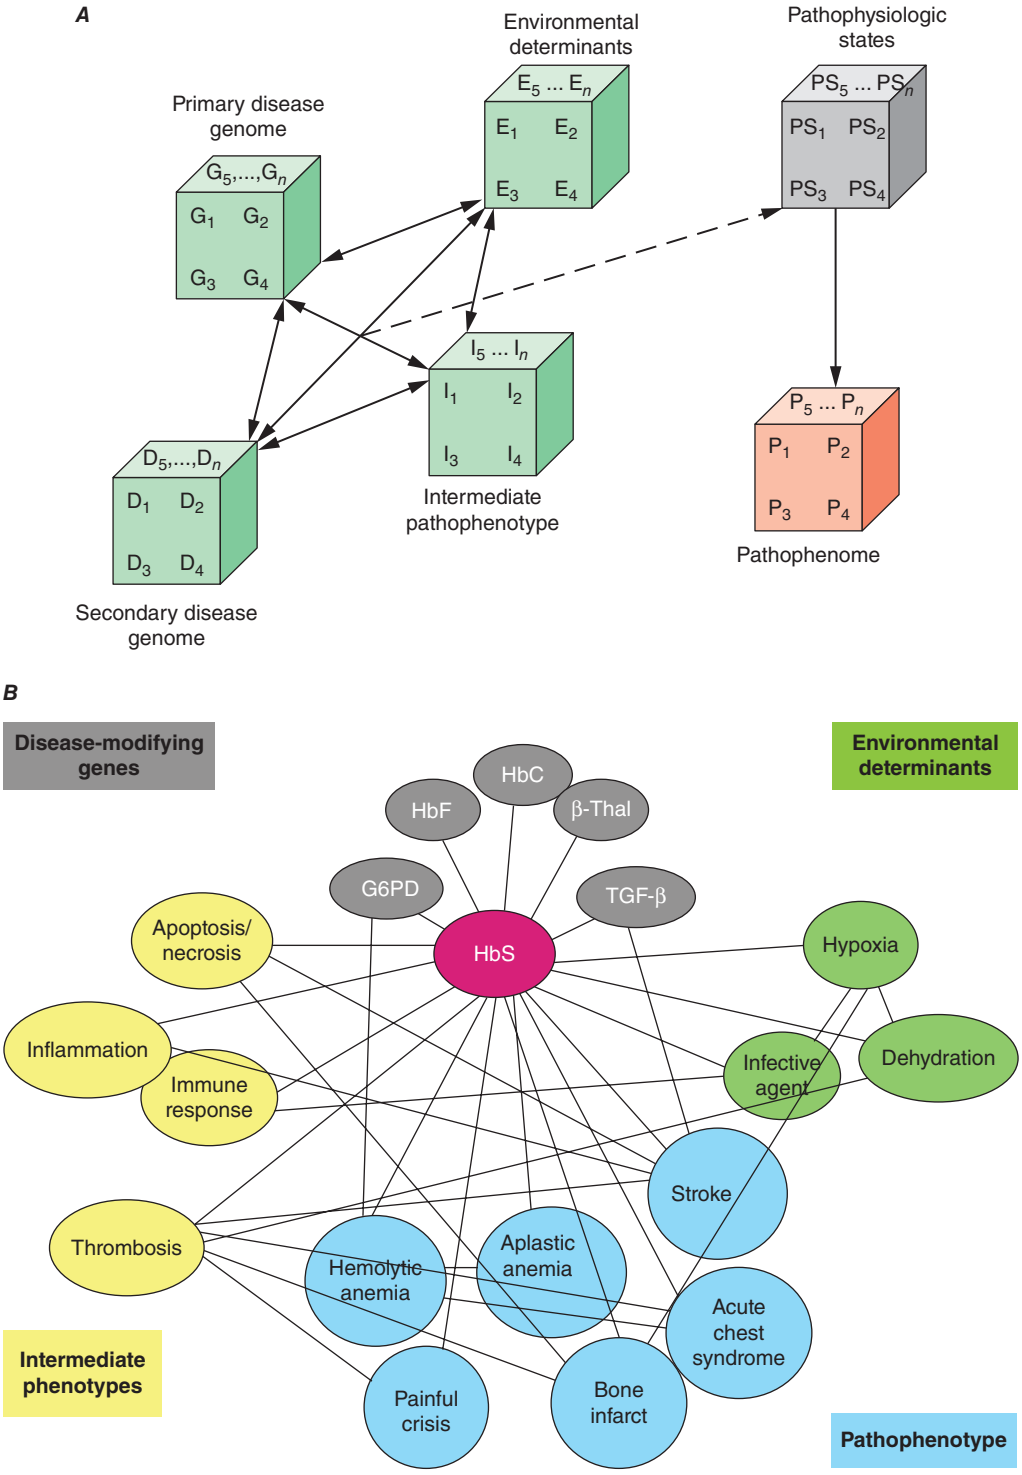

FIGURE 486-3 ***A.*** Theoretical human disease network illustrating the relationships among genetic and environmental determinants of the pathophenotypes. Key: D, secondary disease genome or proteome; E, environmental determinants; G, primary disease genome or proteome; I, intermediate phenotype; PS, pathophysiologic states leading to P, pathophenotype. ***B.*** Example of this theoretical construct applied to sickle cell disease. Key: Red, primary molecular abnormality; gray, disease-modifying genes; yellow, intermediate phenotypes; green, environmental determinants; blue, pathophenotypes. *(Reproduced with permission from J Loscalzo et al: Human disease classification in the postgenomic era: A complex systems approach to human pathobiology. Molec Syst Biol 3:124, 2007.)*

would first identify the intermediate pathophenotypes to which a person is predisposed, then determine how and when to intervene to attenuate that adverse predisposition, and finally limit the likelihood that a major organ-specific event will occur. Evidence for the validity of this approach is found in the work of Rzhetsky and colleagues, who reviewed 1.5 million patient records and 161 diseases and found that these disease phenotypes form a network of strong pairwise correlations. This result is consistent with the notion that underlying genetic predispositions to intermediate pathophenotypes form the predicate basis for conventionally defined end-organ diseases.

Regardless of the specific nature of the systems pathobiologic approach used, these analyses will lead to a drastic revision of the way human disease is defined and treated, establishing the discipline of *network medicine, which reflects a fusion of the fields of systems biology and network science in the study of disease.* This will be a lengthy and complicated process but ultimately will lead to better disease prevention and therapy and likely do so from an increasingly personalized, molecularly precise perspective. The analysis of pathobiology from a systems-based perspective is likely to help define specific subsets of patients more likely to respond to particular interventions based on

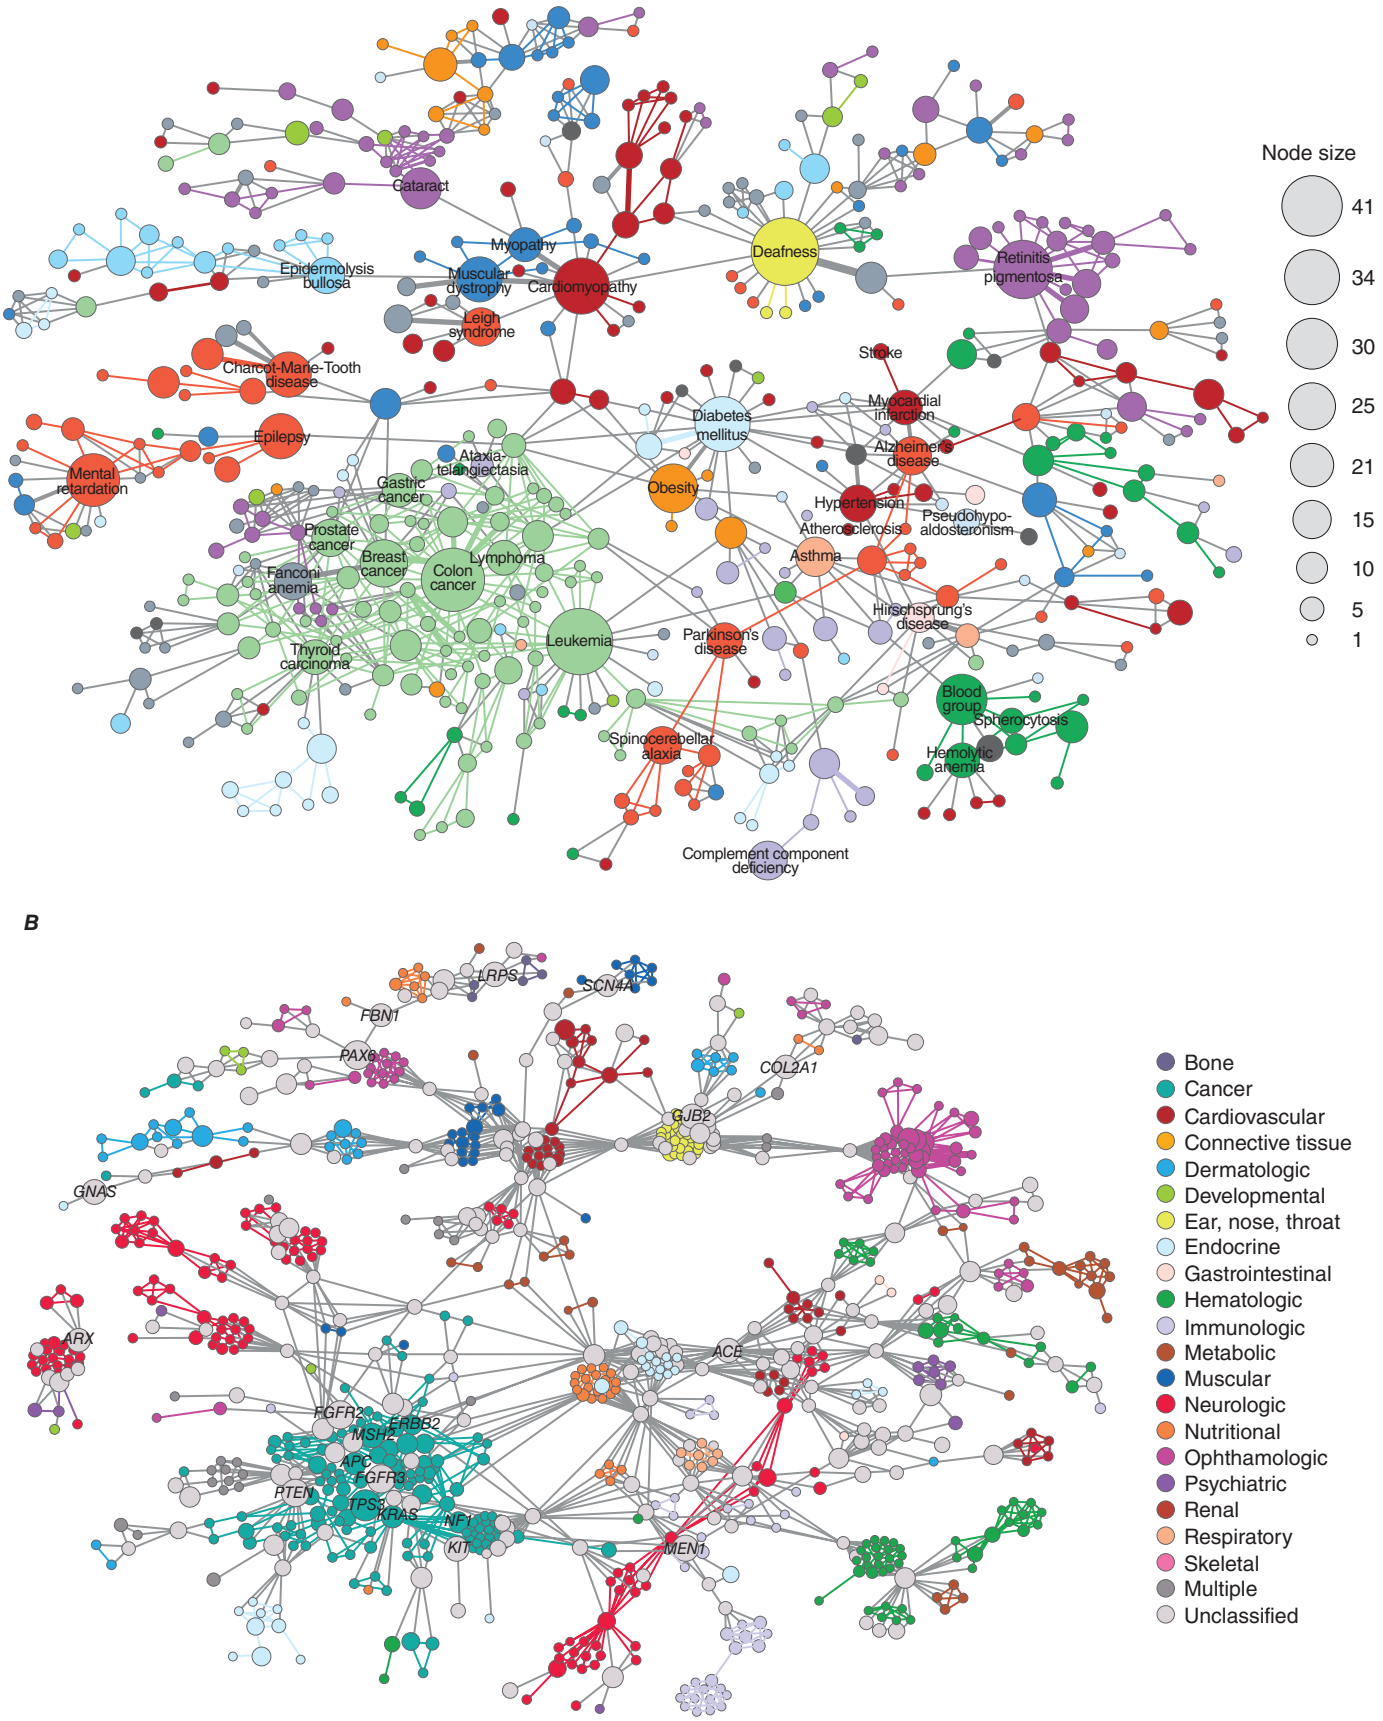

FIGURE 486-4 ***A.*** Human disease network. Each node corresponds to a specific disorder colored by class (22 classes, shown in the key to ***B***). The size of each node is proportional to the number of genes contributing to the disorder. Edges between disorders in the same disorder class are colored with the same (lighter) color, and edges connecting different disorder classes are colored gray, with the thickness of the edge proportional to the number of genes shared by the disorders connected by it. ***B.*** Disease gene network. Each node is a single gene, and any two genes are connected if implicated in the same disorder. In this network map, the size of each node is proportional to the number of specific disorders in which the gene is implicated. *(Reproduced with permission from KI Goh et al: The human disease network. shared disease mechanisms. Although it is unlikely that the extreme of "individualized medicine" will ever be practical (or even desirable), complex diseases can be mechanistically subclassified and interventions may be tailored to those settings in which they are more likely to work. This approach serves as a basis for the development of precision medicine.

487 Emerging Neurotherapeutic Technologies

Jyoti Mishra, Karunesh Ganguly

INTRODUCTION

Neurotherapeutic technologies represent a diverse group of very promising treatment approaches with a common purpose of improving neurologic function. Decades of basic science research have paved the path for these novel technologies that have the potential to transform the lives of patients with neurologic diseases. A key goal is to minimize the consequences of lost abilities, whether they are motor, sensory, or cognitive. A common objective is to also harness the inherent plasticity of the nervous system, regardless of age, and even in the face of a degenerative process.

The technologies described below are the culimination of both an increased understanding of neural plasticity mechanisms in both the intact and the injured nervous system as well as advances in technology and computational power. There has been important progress in understanding neural plasticity at the level of the microscale (e.g., cellular and molecular processes), the mesoscale (e.g., between distinct cortical and subcortical areas), and the macroscale (e.g., at the level of brain neworks). While it is also clear that there may be fundamental limits on plasticity—the closing of developmental windows—and repair mechanisms, the brain remains highly plastic regardless of age and even in the face of ongoing injury and/or degenerative processes. Collectively, there is now growing evidence to support neurologic restorative efforts for both "static" (e.g., stroke) and progressive neurologic disorders.

These technologies may not appear, at first glance, directly relevant to traditional medical care, but it is worth noting that clinicians have the most knowledge and experience about the specific disease process, the treatments available, and the expected course of illnesses affecting the nervous system. It is thus critical that neurologic specialists and other clinicians play an important role in the future adoption of these technologies for neurologic rehabilitation. The sections below outline emerging diagnostic and therapeutic approaches that have the potential to transform the lives of patients with neurologic disorders. These include technologies to harness plasticity, neuroimaging, neurostimulation, and brain–machine interfaces.

TECHNOLOGIES TO HARNESS PLASTICITY

Neurologic rehabilitation aims to harness activity-dependent plasticity mechanisms to maximize functional restoration. This principle can be applied to a diverse range of functional domains such as movement control, sensory processing, language, pain, and cognition. For example, recent randomized controlled clinical trials for motor recovery after stroke have suggested that intensity of training may be particularly important for sustained long-term improvements. Moreover, studies of the effects of such training in rodent and nonhuman primate models further suggest that plasticity of cortical "motor maps" as well as the coordinated firing of neurons in remaining networks underlie observed functional improvements with rehabilitation. The incorporation of technology for neurologic rehabilitation has the great potential to revolutionize the delivery of care by significantly increasing access, reducing the burden for adherence to high-intensity regimens, and by maximizing engagement. Below are three examples of how emerging technology can be used to harness neural plasticity and to maximize functional restoration.

ROBOTICS

Rehabilitation robotics for both the upper and the lower limb have the potential to improve motor outcomes after stroke or other forms of brain injury. There is a growing recognition that focused training involving a range of tasks might be important for improved functional outcomes. While it remains unclear exactly when such training might be optimal after the initial stroke and during the early recovery period, such training likely has a role in both the acute and the chronic periods after stroke; maintenance therapy may also guard against known declines in function over time. Notably, the delivery of intensive training is a great challenge from both the perspective of the health care system and each patient. Outside of clinical trials, such a training program can be quite difficult to implement and maintain. It can also be costly and require significant effort.

Motor rehabilitation using robotics has been developed and tested for both the upper limb and the lower limb. Such robotic therapies have often focused on the delivery of high-intensity movement practice that can surpass what is possible via existing standards of care. Moreover, robotic systems are capable of precisely measuring movement parameters (e.g., the kinematics of the movements) and providing quantitative feedback regarding the changes in performance during the training period. A particular focus has been on maximal patient engagement and recruitment of attentional and reward pathways, both of which are increasingly recognized to drive neural plasticity. Continued advances in design and the user interface will ensure maximal comfort and sustained effort. For example, via close monitoring of performance and movement parameters, the system can provide assistance at key points in order to minimize fatigue and to ensure maximal engagement. Moreover, antigravity support of the upper limb can allow practice and task engagement even in the presence of severe weakness; this would be extremely challenging and labor intensive under current standards of care. Recent analysis also suggests that robotic devices may at least match outcomes realized with existing standards of care. However, rehabilitation robotics may also provide more precise feedback and permit novel quantitative rehabilitation approaches.

Figure 487-1 shows one example of an upper-limb robotic exoskeleton device that is currently being evaluated for training after stroke. A recent randomized, multicenter trial compared treatment with this exoskeleton system against conventional therapy provided by physical and occupational therapists. Participants were enrolled in the chronic phase and all had moderate-to-severe deficits; the groups underwent three sessions per week over an 8-week period. For robotic training, subjects trained with games to improve mobilization and to practice activities of daily living. This study provided evidence that both conventional and robotic therapy could improve function in patients with chronic stroke. Multiple studies have also

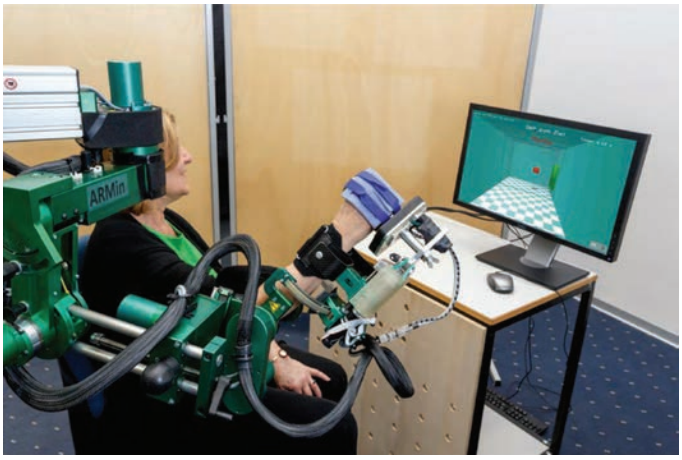

FIGURE 487-1 Photograph of a subject interacting with a complex upper-limb exoskeleton and a virtual reality system. *(From U Keller et al: Robot-Assisted Arm Assessments in Spinal Cord Injured Patients: A Consideration of Concept Study. PLoS One 10:e0126948, 2015.)*

found similar gains when using either conventional or traditional approaches. Thus, a growing body of research supports the idea that such devices might complement conventional approaches to rehabilitation. Future work will need to define how rehabilitation robotics can optimally use adaptive and quantitative methods to further augment the recovery process.

VIRTUAL AND AUGMENTED REALITY

Therapeutic approaches using virtual reality (VR) and augmented reality (AR) aim to treat neurologic illnesses by specifically and quantitatively altering a patient's subjective experiences and interactions with the environment. Core components of both are advanced hardware and computational methods to generate simulated, yet realistic, perceptions. While some applications permit users to dynamically change the viewed perspective, other applications are designed to allow interactions among multiple users. Visual feedback is often a key component; this can include simple computer monitors or more immersive "head-mounted" viewers that modify the simulation based on changes in perspective. Tracking of movements (e.g., hand and head position) is often included. Multiple methods are used to allow a user to interact with the environment; interactions can be guided by straightforward means such as a keyboard, mouse, or even a joystick. More immersive methods are also frequently used. For example, gloves with embedded sensors and haptic inputs can allow the user's hand to be represented in real time in the simulated environment. Moreover, haptic interfaces can provide sensory feedback, allowing patients to interact with and "feel" virtual objects through multiple sensory modalities. A particular strength of these approaches is that therapeutic interventions can be studied in very controlled environments.

VR enables a user to interact with a simulated reality that can be precisely and quantitatively controlled. In addition to allowing patients to dynamically experience an altered reality, it can simultaneously monitor a subject's behaviors and responses. Such monitoring can allow precise measurements of clinically relevant parameters (e.g., motor actions, perception, cognitive processing) and can also be applied in specific rehabilitation training to achieve functionally meaningful goals. A growing body of literature indicates that VR environments can be tailored to individual needs and preferences, thereby maximizing engagement, motivation, and adaptation to ensure sufficient difficulty of tasks. VR environments can be designed to create powerful "gaming" platforms that are actually targeting clinically relevant parameters. For example, the upper-limb robotic systems described previously are frequently combined with VR environments that allow interaction with virtual objects.

In contrast to VR, AR overlays an artificial filter over a subject's view of the actual physical world, thus providing an "augmented" or enhanced view of the world around. AR is being tested in a diverse group of patients with neurologic impairments in the motor, sensory, or cognitive domains. AR may offer a particularly unique rehabilitation intervention for stroke patients. It is widely known that brain injuries limit patients' physical interaction with their environments. Furthermore, physical and cognitive impairments may limit social interactions. Such impoverished experiences are likely to be present during both the acute and the chronic phases. Importantly, there is clear basic scientific evidence that environmental enrichment can be a key component of rehabilitation; such enrichment may offer additive benefits to the often-limited formal rehabilitation sessions per week. Consistent with this are clinical studies suggesting that motor and cognitive outcomes may suffer when interactions with the environment are reduced; AR may be capable of increasing enrichment. For example, in the case of spatial neglect after stroke, the impaired modality may be accounted for using AR methods. Similarly, physical impairments that limit walking speeds can also limit visual feedback; both AR and VR can be used to enhance visual feedback during gait training.

Figure 487-2 shows a recent innovative application of AR for the treatment of "phantom limb" pain. A subset of both upper-limb and lower-limb amputees experiences painful sensations that appear to originate from the missing limb. Past research has suggested that mirror therapy can be an effective treatment for phantom limb pain. During mirror therapy treatments, patients move their healthy arm in front of a mirror in order to produce a perception of movements of the missing limb. Previous studies have suggested that maladaptive plasticity of affected sensory cortices may be treated with mirror therapy. Importantly, in comparison to mirror therapy, AR-based therapy for phantom limb pain can be based on movements of the affected limb, i.e., using the remaining portion of the limb as opposed to the unaffected contralateral limb. This study demonstrated a novel treatment in which "phantom motor execution" is enabled using sophisticated machine-learning algorithms. More specifically, the study "decoded" phantom limb movements by measuring electromyogram (EMG) activity at the stump. Importantly, while the distal muscles responsible for movements were lost as a result of amputation, the remaining EMG activity could be used to predict presumed distal limb movements. As shown in Fig. 487-2, these inferred movements were projected onto an AR screen to create the perception of limb movements. The study showed that a subset of patients with long-term refractory phantom limb pain could experience a significant reduction in pain levels after using the AR system.

NEUROGAMING

Computerized programs that harness the power of video games have shown some evidence for ameliorating deficits in visual perception, age-related degeneration, and neuropsychiatric disorders. An essential feature of effective video game training is the progressive adjustment of the level of difficulty in line with the cognitive improvement of the patient. Important areas of active research include ways to enhance sustainability of neurogame training over long time periods and improving training *transfer*, i.e., the generalizability of task-specific training in one cognitive domain to more broad-based functional improvements. By leveraging video game technology, neurogames allow for dynamic user interaction and maintain user engagement across multiple sessions over several days of training. Important game mechanics include repetitive practice, performance-adaptive challenges, and several layers of reward feedback—from moment-to-moment point rewards to reward milestones over multiple sessions.

Notably, neurogames have therapeutic potential as they can be targeted to specific neurocognitive deficits. For instance, games have shown significant benefits in aging, by targeting speed of processing and training the abilities to multitask and suppress distractions. In each case, selective targeting is achieved by focusing the adaptive challenges to the neurocognitive domain of interest. Duration of response time windows available to the user or the level of interference are selectively targeted in the case of speed of processing training and interference training, respectively. More recent research demonstrated that it is possible to engender focused circuit neuroplasticity using such selective targeting in neurogaming. For example, older adults learned to

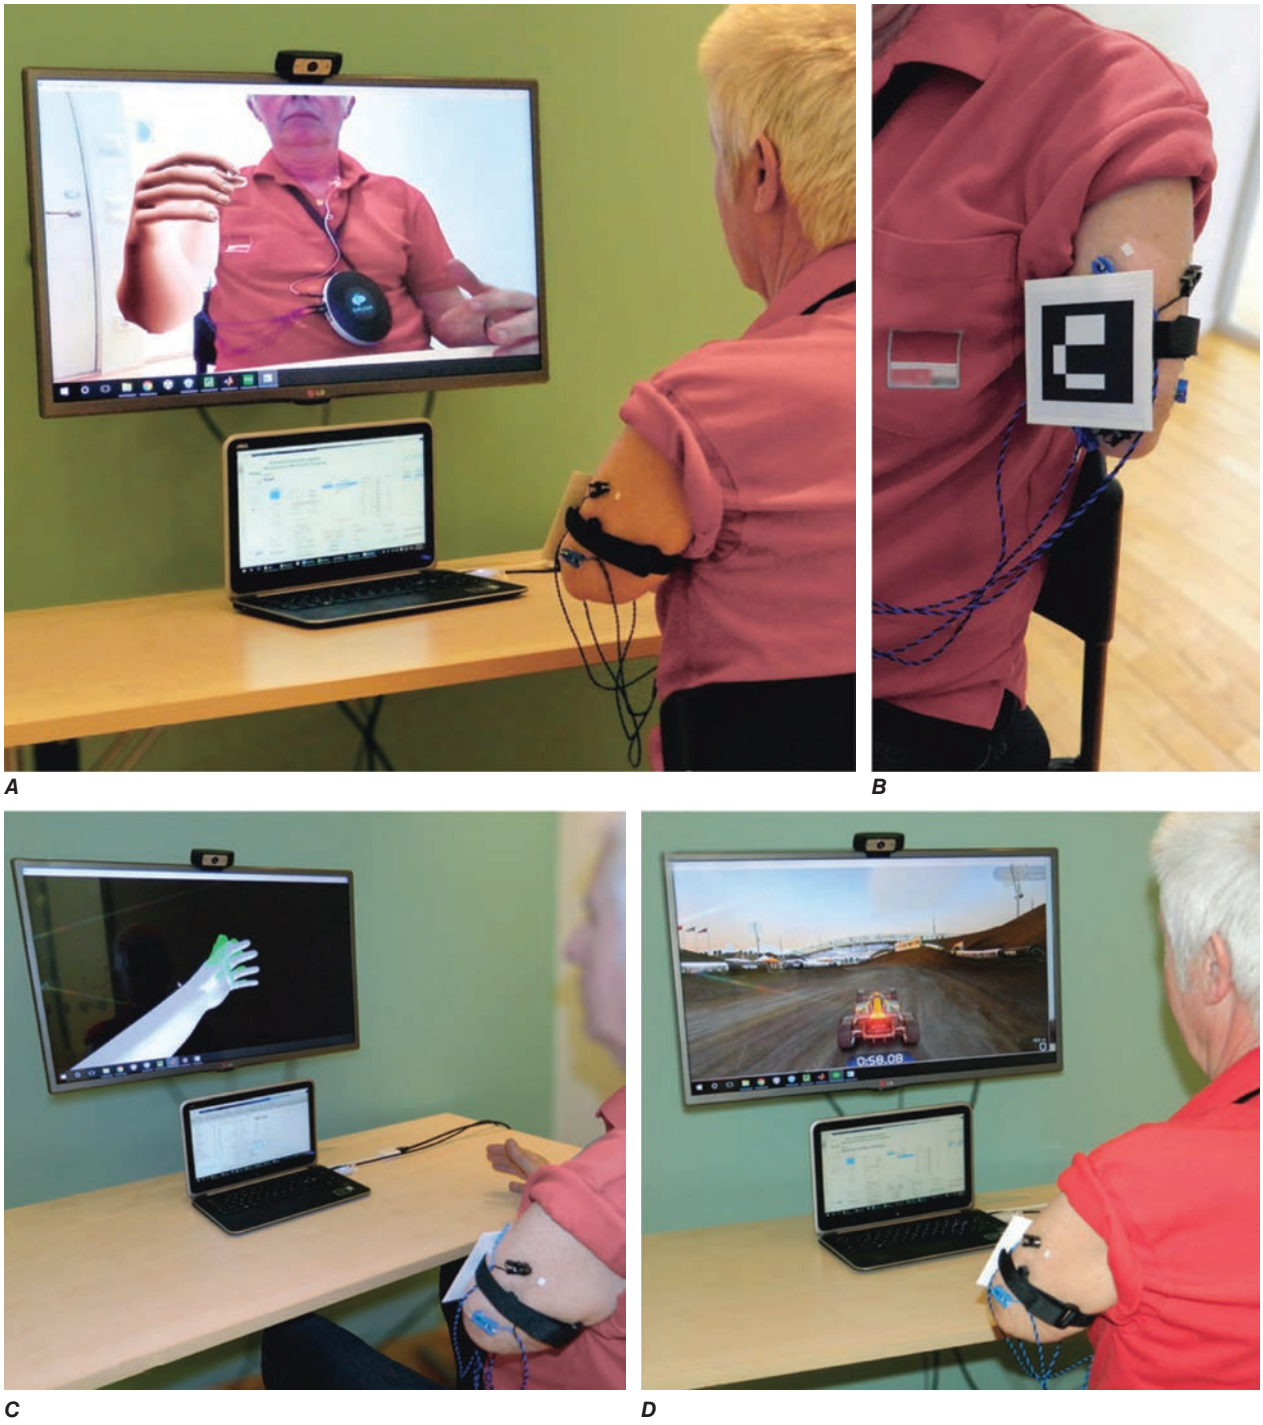

FIGURE 487-2 Augmented reality (AR) for phantom limb pain. ***A.*** A patient is shown a live AR video. ***B.*** EMG electrodes placed over the stump record muscle activation during training. ***C.*** The patient matches target postures during rehabilitation. ***D.*** Patient playing a game in which a car is controlled by "phantom movements." *(M Ortiz-Catalan et al: Phantom motor execution facilitated by machine learning and augmented reality as treatment for phantom limb pain: A single group, clinical trial in patients with chronic intractable phantom limb pain. Lancet 388:2885, 2016.)*

adaptively perform within progressively more challenging distractor environments. Neuroplasticity selective to distractor processing was evidenced in this study at both the microscale, i.e., at the resolution of single neuron spiking in sensory cortex, as well as macroscale, i.e., electroencephalography (EEG)-based event-related potential recordings.

Video games have also shown promise in the treatment of visual deficits such as amblyopia, and in cognitive remediation in neuropsychiatric disorders such as schizophrenia. However, while the evidence base has been encouraging in small-sample randomized controlled studies (RCTs), larger RCTs are needed to demonstrate definitive therapeutic benefit. This is especially necessary as the commercial *brain training* industry continues to make unsubstantiated claims of the benefits of neurogaming; such claims have been formally dismissed by the scientific community. Like any other pharmacologic or device-based therapy, neurogames need to be systematically validated in multiphase RCTs establishing neural target engagement and documenting cognitive and behavioral outcomes in specific disorder populations.

Generalizability of training benefits from task-specific cognitive outcomes to more broad-based functional improvements remains the holy grail of neurogaming. Next-generation neurogames will aim to integrate physiologic measures such as heart rate variability (an index of physical exertion), galvanic skin responses, and respiration rate (indices of stress response), and even EEG-based neural measures. The objectives of such multimodal biosensor integration are to enhance the "closed-loop mechanics" that drive game adaptation and hence improve therapeutic outcomes and perhaps result in greater

generalizability. These complex, yet potentially more effective, neurogames of the future will need rigorous clinical study for demonstration of validity and efficacy.

NEUROIMAGING

NEUROIMAGING OF CONNECTIVITY

Multimodal neuroimaging methods including functional magnetic resonance imaging (fMRI), EEG, and magnetoencephalography (MEG) are now being investigated as tools to study functional connectivity between brain regions, i.e., extent of correlated activity between brain regions of interest. Snapshots of functional connectivity can be analyzed while an individual is engaged in specific cognitive tasks or during rest. Resting-state functional connectivity (rsFC) is especially attractive as a robust, task-independent measure of brain function that can be evaluated in diverse neurologic and neuropsychiatric disorders. In fact, methodologic research has shown that rs-fMRI can provide more reliable brain signals of energy consumption than specific task-based fMRI approaches.

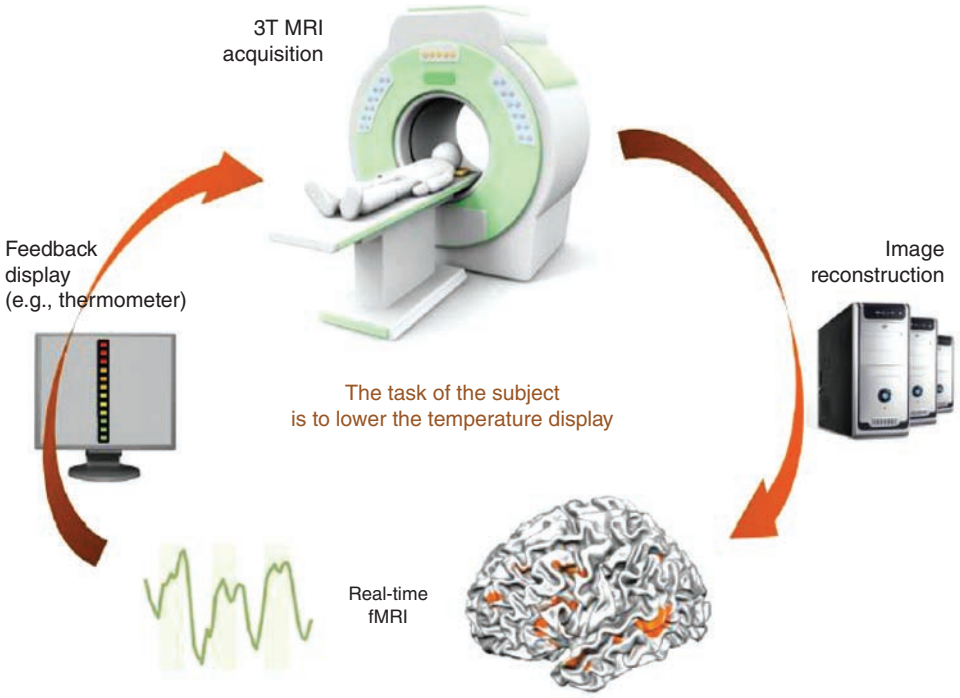

FIGURE 487-3 Neurofeedback using functional MRI. *(From T Fovet et al: Translating neurocognitive models of auditory-visual hallucinations into therapy. Front Psychiatry 7:103, 2016.)*

In recent years, there has been a surge of research to identify robust rsFC-based biomarkers for specific neurologic and neuropsychiatric disorders and thereby inform diagnoses, and even predict specific treatment outcomes. For many such disorders, the network-level neurobiologic substrates that correspond to the clinical symptoms are not known. Furthermore, many are not unitary diseases, but rather heterogeneous syndromes composed of varied co-occurring symptoms. Hence, the research quest for robust network biomarkers for complex neuropsychologic disorders is challenging and still in its infancy; yet some studies have made significant headway in this domain. For example, in a large multisite cohort of ~1000 depressed patients, Drysdale et al. (2017) showed that rsFC measures can subdivide patients into four neurophysiologic "biotypes" with distinct patterns of dysfunctional connectivity in limbic and frontostriatal networks. These biotypes were associated with different clinical-symptom profiles (combinations of anhedonia, anxiety, insomnia, anergia, etc.) and had high (>80%) diagnostic sensitivity and specificity. Moreover, these biotypes could also predict responsiveness to transcranial magnetic stimulation (TMS) therapy. Another recent study demonstrated utility of rsFC measures to predict diagnosis of mild traumatic brain injury (mTBI), which is clinically challenging by conventional means.

Apart from fMRI-based measures of rsFC, EEG- and MEG-based rsFC measures are also being actively investigated, as these provide a relatively lower-cost alternative to fMRI. While EEG is of lowest cost, it compromises on spatial resolution. The major strength of MEG is its ability to provide more accurate source-space estimates of functional oscillatory coupling than EEG as well as provide measures at various physiologically relevant frequencies (up to 50 Hz shown to be clinically useful). In this regard, EEG/MEG are complementary to fMRI, which can only be used to study slow activity fluctuations (i.e., <0.1 Hz); the potential for EEG/MEG modalities to provide valid diagnostic biomarkers is currently underexploited and requires further study.

CLOSED-LOOP NEUROIMAGING

Neuroscientific studies to-date are predominantly designed as "open-loop experiments," interpreting the neurobiologic substrates of human behavior via correlation with simultaneously occurring neural activity. In recent years, advances in real-time signal processing have paved the way for "closed-loop neuroimaging," wherein humans can directly manipulate experiment parameters in real-time based on specific brain signals **(Fig. 487-3)**. Closed-loop imaging methods can not only advance our understanding of dynamic brain function but also have therapeutic potential. Humans can learn to modulate their neural dynamics in specific ways when they are able to perceive (i.e., see/hear) their brain signals in real-time using closed-loop neuroimaging-based neurofeedback. Early studies showed that such neurofeedback learning and resulting neuromodulation could be applied as therapy for patients suffering from chronic pain, motor rehabilitation in Parkinson's and stroke patients, modulation of aberrant oscillatory activity in epilepsy, and improvement of cognitive abilities such as sustained attention in healthy individuals and patients with attention-deficit hyperactivity disorder (ADHD). It has also shown potential for deciphering state-of-consciousness in comatose patients, wherein a proportion of vegetative/minimally conscious patients can communicate awareness via neuroimaging-based mental imagery.

Closed-loop neuroimaging therapeutic studies have utilized real-time fMRI, EEG, and MEG methods. It is common for neural signals to be extracted from specific target brain regions for neuromodulation. However, given that distributed neural networks underlie behavioral deficits, new studies have also explored neurofeedback on combinatorial brain signals from multiple brain regions extracted using multivariate pattern analysis (MVPA). While early studies indicate therapeutic potential, clinical RCTs of closed-loop neuroimaging neurofeedback have shown mixed results. This may largely be because of the individual heterogeneity in neuropsychiatric disorders such that there is no one-size-fits-all therapy. Closed-loop neuroimaging-based therapies need to be better personalized to the pre-intervention cognitive and neurophysiologic states of the individual, and a better understanding needs to be developed regarding learning principles and mechanisms of self-regulation underlying neurofeedback. Clinical practitioners applying these methods also need better education on the hardware/software capabilities of these brain–computer interfaces to maximize patient outcomes.

NONINVASIVE BRAIN STIMULATION

Noninvasive brain stimulation (NIBS) is widely recognized as having great potential to modulate brain networks in a range of neurologic and psychiatric diseases; it is currently approved by the U.S. Food and Drug

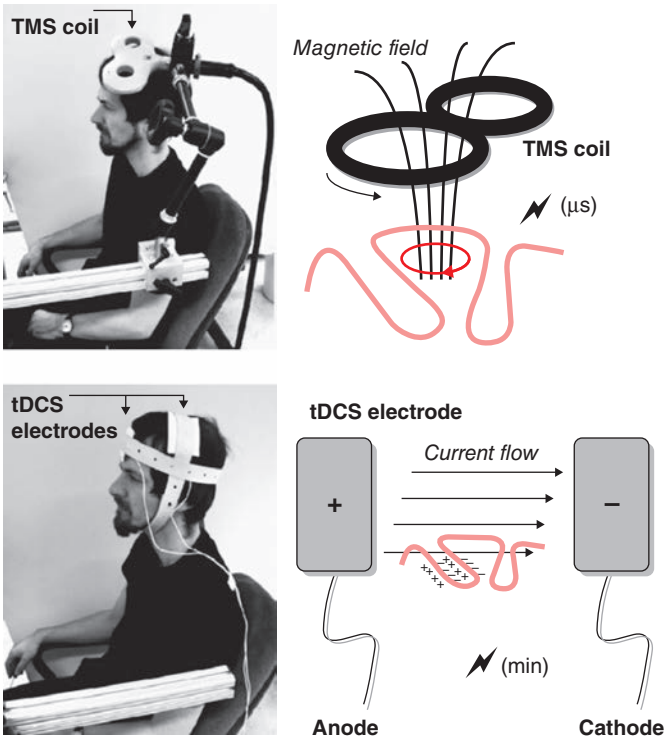

FIGURE 487-4 Illustration of TMS and tDCS setups. The upper panels show a TMS setup. Coils generate magnetic fields that can in turn generate electrical fields in the cortical tissue. The lower panels show a tDCS setup. The electrical current is believed to flow from the anode (+) to the cathode (–) through the superficial cortical areas leading to polarization. *(Reproduced with permission from R Sparing, FM Mottaghy: Noninvasive brain stimulation with transcranial magnetic or direct current stimulation [TMS/tDCS]—From insights into human memory to therapy of its dysfunction. Methods 44:329, 2008.)*

Administration (FDA) as a treatment for depression. Importantly, there is a very large body of basic research indicating that neuromodulation of the nervous system with electrical stimulation can have both short-term and long-term effects. While transcranial magnetic stimulation (TMS) uses magnetic fields to generate electrical currents, transcranial direct current stimulation (tDCS), in contrast, is based on direct stimulation using electrical currents applied at the scalp **(Fig. 487-4)**. TMS induces small electrical currents in the brain by magnetic fields that pass through the skull; it is known to be painless and therefore widely used for NIBS. Animal research suggests that anodal tDCS causes a generalized reduction in resting membrane potential over large cortical areas, whereas cathodal stimulation causes hyperpolarization. Prolonged stimulation with tDCS can cause an enduring change in cortical excitability under the stimulated regions. Further, changes in resting-state fMRI-based activity and functional connectivity have also been observed post-tDCS. Notably, there is uncertainty regarding precisely how much electrical current is able to penetrate through the skull and modulate neural networks. Indeed, recent work has found that typical stimulation paradigms may not generate sufficient electrical fields to modulate neural activity; an alternate possibility is that peripheral nerves may be modulated and thus affect neural activity.

Neuromodulation via stimulation techniques such as tDCS and TMS have shown promise as methods to improve motor function after stroke; there are a growing number of studies demonstrating functional benefits of combining physical therapy with brain stimulation. Two commonly utilized TMS paradigms include low-frequency "inhibitory" stimulation of the healthy cortex or high-frequency "excitatory" stimulation of the injured hemisphere. Each of these two approaches aims to modify the balance of reciprocal inhibition between the two hemispheres after stroke. A meta-analysis of randomized controlled trials published over the past decade found a significant beneficial effect on motor outcomes. Unfortunately, a recent large multicenter trial to assess the long-term benefits of TMS on motor recovery after stroke (NICHE trial) did not find a benefit at the population level. Ongoing research aims to better understand how stimulation can directly affect neural patterns and thus allow more customization of stimulation—past trials did not record the neural responses to stimulation.

TMS and tDCS interventions are also being applied in psychiatric disorders. A substantial body of evidence supports the use of TMS as an antidepressant in major depressive disorder (MDD). TMS is also being investigated for its potential efficacy in posttraumatic stress disorder (PTSD), obsessive compulsive disorder (OCD), and treatment of auditory hallucinations in schizophrenia. Various repetitive TMS (rTMS) protocols have shown efficacy in major depression. These include both low-frequency (≤1 Hz) and high-frequency (10–20 Hz) rTMS stimulation over the dorsolateral prefrontal cortex (DLPFC). Mechanistically, low-frequency rTMS is associated with decreased regional cerebral blood flow while high-frequency rTMS elicits increased blood flow, not only over the prefrontal region where the TMS is applied, but also in associated basal ganglia and amygdala circuits. Notably, the differential mechanisms of the low- vs. high-frequency rTMS protocols are associated with mood improvements in different sets of MDD patients, and patients showing benefits with one protocol may even show worsening with the other, again pointing to individual heterogeneity in network function. EEG-guided TMS is also being investigated in psychiatric disorders, for instance, individual resting alpha-band (8–12 Hz) peak frequency to determine TMS stimulation rates. With respect to transcranial electrical stimulation in psychiatry, tDCS is the most commonly used protocol. In major depression, there is a documented imbalance in left vs. right DLPFC activity; hence, differential anodal vs. cathodal tDCS in the left vs. right prefrontal cortex may be a potentially efficacious approach. Interestingly while meta-analysis shows promise for NIBS methods in psychiatric illness, large RCTs have failed to generate effects compared to placebo treatment. Future success may require careful personalized targeting based on network dynamics and refinement of protocols to accommodate combinatorial treatments.

IMPLANTABLE NEURAL INTERFACES INCLUDING BRAIN–MACHINE INTERFACES

Fully implantable clinically relevant neural interfaces that can improve function already exist. Cochlear implants, for example, are sensory prostheses that can restore hearing in deaf patients. Environmental sounds are processed in real-time and then converted into patterned stimulation delivered to the cochlear nerve. Importantly, even while the patterned stimulation remains the same, there are gradual improvements in the perception of speech and other complex sounds over a period of several months after device implantation. Activity-dependent sculpting of neural circuits is hypothesized to underlie the observed perceptual improvements. Similarly, the development of deep-brain stimulation (DBS) was based on decades of work showing that surgical lesions to specific nuclei could alleviate tremor and bradykinesia symptoms in animal models. DBS involves chronic implantation of a stimulating electrode that targets specific neural structures (e.g., subthalamic nuclei or the globus pallidus in Parkinson's disease). At least for movement disorders, it is commonly thought that targeted areas are functionally inhibited by the chronic electrical stimulation.

IMPLANTABLE DEVICES FOR NEUROMODULATION

There has been recent progress in the development of implantable neural interfaces to treat neurologic and psychiatric illnesses. For example, for patients with refractory focal epilepsy and clearly identified seizure foci, invasive "responsive stimulation" has now been FDA approved. Responsive stimulation is grounded on principles of closed-loop stimulation based on real-time monitoring of brain oscillations; specifically, the device aims to detect the earliest signatures of the onset of a seizure, usually at a stage that is not symptomatic, and then deliver focused electrical stimulation to prevent further progression and generalization. A large, randomized control trial of this device was performed in patients with intractable focal epilepsy; they were assigned to either sham or active stimulation in response to seizure detection. There was a significant reduction in seizure frequency in the

stimulation group, but it was rare for patients to become seizure free. There were also modest improvements in quality of life. Notably, there was a small, elevated risk of hemorrhage associated with the device. In addition to providing clinicians with another treatment option, this device has offered important avenues for research and further optimization. For example, it is now possible to monitor subclinical and clinical seizures and intracranial EEG in patients with chronic epilepsy. This has resulted in new knowledge about the association of seizures with circadian rhythms and sleep. It is also anticipated that a better understanding of the triggers of seizures and the development of better stimulation algorithms, based on real-world data, can ultimately lead to more effective treatments.

There is also great interest in the development of treatments for refractory depression. One area of focus has been on the development of DBS to treat depression. While early smaller studies were quite promising, a larger study failed to find benefits at the population level. Subsequent analysis has suggested the possibility that more precise tailoring of stimulation to each individual is warranted, both at the level of specific pathways identified through neuroimaging as well as network activity biomarkers. This approach is based on the hypothesis that tailoring stimulation parameters to each individual may be more promising. Recent studies have, in fact, supported the notion that individualized patterns of network activity are predictive of a patient's symptoms and how he or she might respond to stimulation. There are now planned studies that aim to tailor stimulation to each individual with severe depression.

BRAIN–MACHINE INTERFACES FOR PARALYSIS

Brain–machine interfaces (BMIs) represent a more advanced neural interface that aims to restore motor function. Multiple neurologic disorders (e.g., traumatic and nontraumatic spinal cord injury, motor-neuron disease, neuromuscular disorders, and strokes) can result in severe and devastating paralysis. Patients cannot perform simple activities and remain fully dependent for care. In patients with high cervical injuries, advanced amyotrophic lateral sclerosis (ALS), or brainstem strokes, the effects are especially devastating and often leave patients unable to communicate. While there has been extensive research into each disorder, little has proven to be clinically effective for rehabilitation of long-term disability. BMIs offer a promising means to restore function. In the patients described above, while the pathways for transmission of signals to muscles are disrupted, the brain itself is largely functional. Thus, BMIs can restore function by communicating directly with the brain. For example, in a "motor" BMI, a subject's intention to move is translated in real-time to control a device. As illustrated in **Fig. 487-5**, the components of a motor BMI include: (1) recordings of neural activity, (2) algorithms to transform the neural activity into control signals, (3) an external device driven by these control signals, and (4) feedback regarding the current state of the device.

Many sources of neural signals can be used in a BMI. While EEG signals can be obtained noninvasively, other neural signals require invasive placement of electrodes. Three invasive sources of neural signals include electrocorticography (ECoG), action potentials or spikes, and local field potentials (LFP). Spikes and LFPs are recorded with electrodes that penetrate the cortex. Spikes represent high-bandwidth signals (300–25,000 Hz) that are recorded from either single neurons ("single-unit") or multiple neurons ("multiunit" or MUA). LFPs are the low-frequency (~0.1–300 Hz) components. In contrast, ECoG is recorded from electrodes that are placed on the cortical surface. ECoG signals may be viewed as an intermediate-resolution signal in comparison with spikes/LFPs and EEG. It is worth noting that there is still considerable research into the specific neural underpinning of each signal source and what information can be ultimately extracted regarding neural processes.

A critical component of a BMI is the transform of neural activity into a reliable control signal. The decoder is an algorithm that converts the neural signals into control signals. One important distinction between classes of decoders is biomimetic versus nonbiomimetic. In the case of biomimetic decoders, the transform attempts to capture the natural relationship between neural activity and a movement parameter. In contrast, nonbiomimetic decoders can be more arbitrary transforms between neural activity and prosthetic control. It had been hypothesized that learning prosthetic control with a biomimetic decoder is more intuitive. Recent evidence, however, reveals that learning may be important for achieving improvements in the level of control over an external device (e.g., a computer cursor, a robotic limb) for either type of decoder. This may be similar to learning a new motor skill.

A central goal of the field of BMIs is to improve function in patients with permanent disability. This can consist of a range of communication and assistive devices such as a computer cursor, keyboard control, wheelchair, or robotic limb. In the ideal scenario, the least invasive method of recording neural signals would allow the most complex level of control. Moreover, control should be allowed in an intuitive manner that resembles the neural control of our natural limbs. There is currently active research into developing and refining techniques to achieve the most complex control possible using each signal source. One measure of complexity is the degrees of freedom that are controlled. For example, control of a computer cursor on the screen (i.e., on the *x* and *y* axis) represents two degrees of freedom (DOF). Control of a fully functional prosthetic upper arm that approaches our natural range of motion would require >7 DOF. If the functionality of the hand and fingers is included, then an even more complex level of control would be required. There has been a large body of research on the use of noninvasive recording of EEG signals. Studies suggest that two-DOF control using EEG is feasible. There are also promising reports of patients with advanced ALS communicating via email using EEG-based BCIs. Known limitations of EEG-based BCIs include their signal-to-noise ratio (due to filtering of neural signals by bone and skin) and contamination by muscle activity. Ongoing research aims to test usability in a more general nonresearch setting as well as targeted use in patients with disability.

Numerous studies now also indicate that BMIs using invasive recording of neural signals can allow rapid control over devices with multiple DOF. The clear majority of this research has been conducted using recordings of spiking activity via implanted microelectrode arrays. Initial preclinical studies were performed in able-bodied nonhuman primates. More recently, there have been numerous examples of human subjects with a range of neurologic illnesses (e.g., brainstem stroke, ALS, spinal cord injury) who have demonstrated the actual use of implantable neural interfaces. This includes demonstrations of both the control of communication interfaces as well as robotic limbs. Pilot clinical trials of

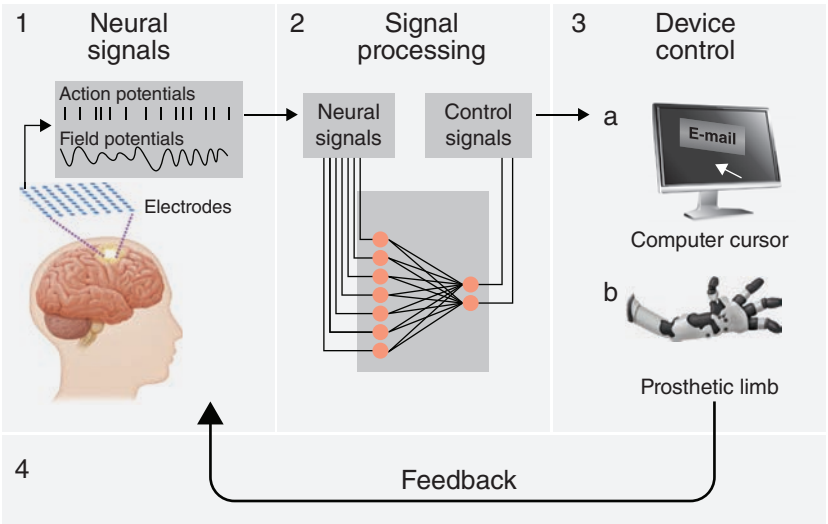

FIGURE 487-5 Components of a brain–machine interface (BMI). *(Reproduced with permission from A Tsu et al: Cortical neuroprosthetics from a clinical perspective. Neurobiol Dis 83:154, 2015.)*

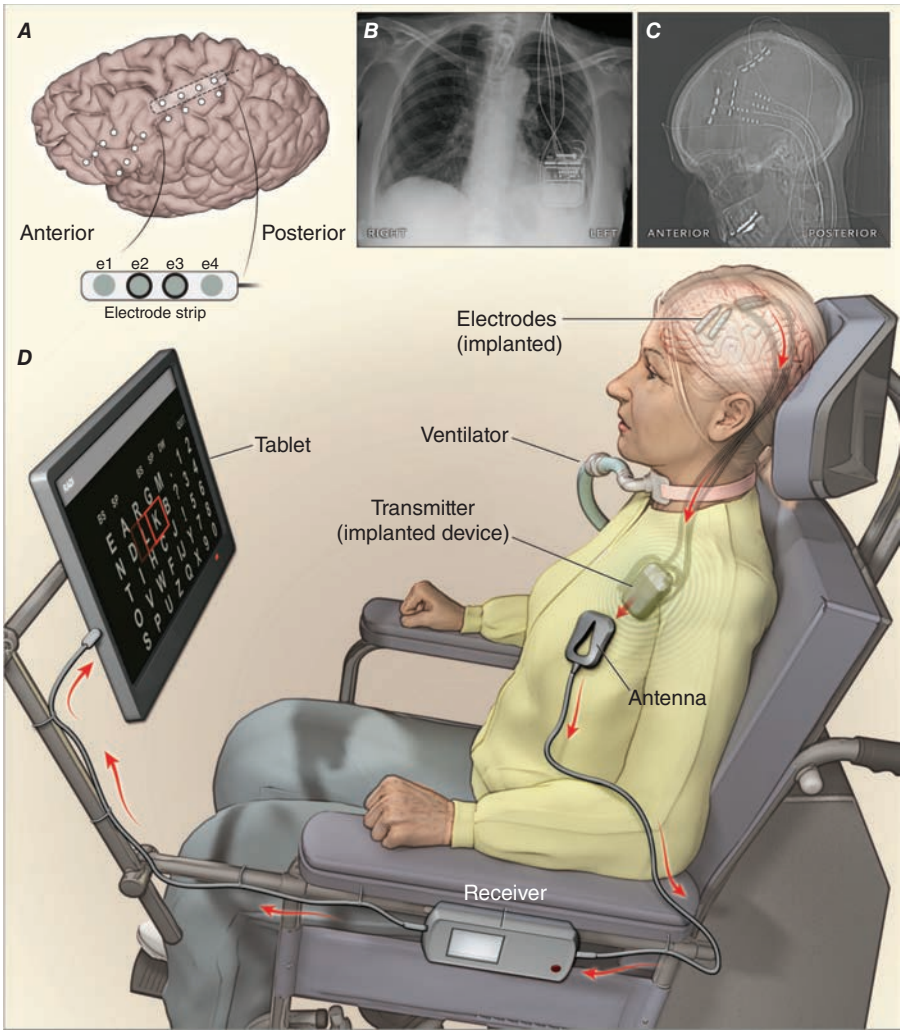

FIGURE 487-6 Illustration of an ALS patient with a fully implanted communication interface. ***A*** Illustration of the location of electrodes on the brain. ***B*** X-ray of chest showing the wireless module. ***C*** X-ray of leads and wire routing. ***D*** Schematic of the subject performing a typing task. *(From MJ Vansteensel et al: Fully implanted brain–computer interface in a locked-in patient with ALS. N Engl J Med 375:2060, 2016. Copyright © 2016 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

BCIs based on invasive recordings of neural signals have further shown that significantly greater rates of communication are possible (e.g., >30 characters per minute). Notably, these BCI devices required a percutaneous connection and were always tested in the presence of research staff. A case study additionally demonstrated that a fully implantable BCI system could allow communication in a locked-in ALS patient **(Fig. 487-6)**. At the time of the study, the patient required mechanical ventilation and could only communicate using eye movements. She was implanted with multiple subdural cortical electrodes; the neural signals were then processed and sent wirelessly to an external augmentative alternative communication (AAC) device. Importantly, she could use the interface with no supervision from research staff.

BMIs have the potential to revolutionize the care of neurologically impaired patients. While in its infancy, there have been multiple proof-of-principle studies that highlight possibilities. Combined basic and clinical efforts will ultimately lead to the development of products that are designed for patients with specific disabilities. As outlined earlier, each signal source has strengths (e.g., noninvasive versus invasive, recording stability) and weaknesses (e.g., bandwidth or the amount of information that can be extracted). With additional research, a more precise delineation of these strengths and weakness should occur. For example, one hypothesis is that control of complex devices with high DOF will only be possible using invasive recordings of high-resolution neural activity such as spikes from small clusters of neurons. However, recent trials using ECoG suggest that its stability might also allow higher DOF control. As these limits become increasingly clear it should allow targeted clinical translational efforts that are geared to specific patient needs and preferences (e.g., extent of disability, medical condition, noninvasive versus invasive). For example, patients with high cervical injuries (i.e., above C4, where the arm and the hand are affected) have rehabilitation needs different from patients with lower cervical injuries (i.e., below C5–C6, where the primary deficits are the hand and fingers).

488 Machine Learning and Augmented Intelligence in Clinical Medicine

Arjun K. Manrai, Isaac S. Kohane

Machine learning has reshaped our consumer lives, with self-driving vehicles, conversant digital assistants, and machine translation services so ubiquitous that they are at risk of not being considered particularly intelligent for much longer. Will the algorithms underlying these technologies similarly transform the art and practice of medicine? There is hope that modern machine-learning techniques—especially the resurgence of artificial neural networks in deep learning—will foster a sea change in clinical practice that augments both the sensory and diagnostic powers of physicians while, perhaps paradoxically, freeing physicians to spend more time with their patients by performing laborious tasks.

From the birth of artificial intelligence at the Dartmouth Summer Research Project on Artificial Intelligence in 1956 to self-driving vehicles today, machine-learning methods and theory have developed in symbiosis with growing datasets and computational power. In this chapter, we discuss the foundations of modern machine-learning algorithms and their emerging applications in clinical practice. Modern machine-learning techniques are sufficiently capacious as to learn flexible and rich representations of clinical data and are remarkably adept at exploiting spatial and temporal structure in raw data. The newest machine-learning models perform on par with expert physicians or prior state-of-the art models on a variety of tasks, such as the interpretation of images (e.g., grading retinal fundus photographs for diabetic retinopathy), analysis of unstructured text (e.g., predicting hospital readmission from electronic health record notes), and processing of speech (e.g., detecting depression from patient speech). However, many evaluations of machine-learning models occur on tasks that are narrow and unrealistic, and further lack the clinical context that a physician would incorporate. The models themselves are also often divorced from considerations of patient utility. To help ensure these models benefit patients, this chapter aims to bring more physicians into the design and evaluation of machine-learning models by providing an understanding of how modern machine-learning models are developed and how they relate to more familiar methods from the epidemiological literature.

Today, the terms *machine learning* and *artificial intelligence* evoke images distinct from those conjured up by the same terms in the 1950s and the 1980s, and they likely will mean something different in a decade. Computer scientist John McCarthy originally defined artificial intelligence in 1956 as "the broad science and engineering of creating intelligent machines," most often embodied today as computer software. Machine learning can be viewed as the subfield of artificial intelligence encompassing algorithms that extract generalizable patterns from data. This stands in contrast to approaches to create intelligence from human-engineered and explicitly programmed rules that characterized many early applications of artificial intelligence to medicine during the 1970s and 1980s (e.g., expert systems such as INTERNIST-I and MYCIN).

This chapter covers machine-learning methods and applications that may augment physician expertise at the point of care. Many applications of machine learning in health care are therefore not reviewed here, for example algorithms to improve hospital planning, detect insurance fraud, and monitor new drugs for adverse events. Throughout this chapter, we discuss how new machine-learning methods can learn rich representations of both clinical state and patient identity by discovering *how* to represent raw data. At the same time, models largely reflect the data on which they are trained and, thus, may encode and amplify biased prior practices; they may also be brittle in unfamiliar and evolving settings. If machine-learning methods are positioned to tackle problems based on physician needs and are continuously re-assessed, we envisage a future with clinics instrumented with machine-learning tools that augment the ability of physicians to reason precisely and probabilistically over populations at the point of care.

CONCEPTS OF MACHINE LEARNING

TYPES OF MACHINE LEARNING

Many physicians will be familiar with the major types of machine-learning methods from methodologic counterparts discussed in the context of "traditional" statistical and epidemiological modeling. In the current machine-learning and epidemiology literature, much confusion arises over whether a method "belongs" in one camp or the other. More is gained by focusing on the computational and statistical connections, particularly in understanding how new machine-learning methods compare with familiar clinical risk-stratification approaches.

Broadly, there are four major types of machine learning with applications to clinical medicine: (1) supervised learning, (2) unsupervised learning, (3) semi-supervised learning, and (4) reinforcement learning. The four subfields of machine learning differ from one another in both their objectives and the degree to which algorithms have access to labeled examples from which to learn **(Fig. 488-1)**. All four subfields have roots tracing back decades with classical examples and modern counterparts **(Table 488-1)**.

To date, supervised machine-learning approaches have dominated the medical literature and recent deep-learning applications. In supervised learning, paired input and *labeled* output examples are provided together to a machine-learning algorithm that learns what combination (potentially millions) of parameters optimizes a function that predicts

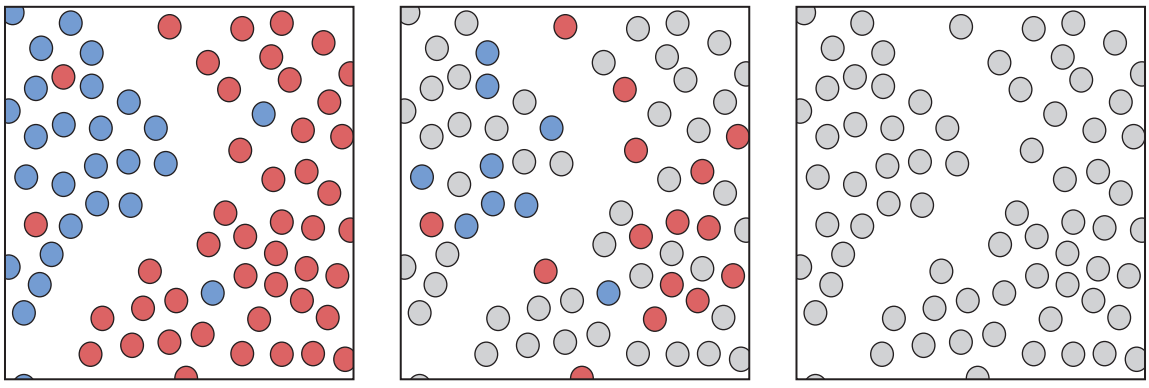

FIGURE 488-1 The subfields of machine learning differ in their access to labeled examples. In supervised learning (*left*), the learning algorithm uses labeled output examples (*red, blue*) to learn a classifier for determining whether a new unlabeled data point is red or blue. Semi-supervised learning methods (*center*) have access to both unlabeled and labeled examples; the unlabeled data help learn a classifier with fewer labeled examples. Unsupervised learning methods (*right*) do not use labels but, rather, identify structure present in the data. *(Reproduced with permission from Luke Melas-Kyriasi.)*

TABLE 488-1 Types of Machine Learning and Clinical Examples

SUBFIELD OF MACHINE LEARNING	DEFINITION	CLASSIC EXAMPLE	CONTEMPORARY EXAMPLE	CLINICAL EXAMPLE
Supervised learning	Methods that use paired input and *labeled* output examples to learn a generalizable function that predicts output labels from input	Logistic regression	Convolutional neural network (CNN)	Histopathological detection of lymph node metastases in breast cancer patients
Unsupervised learning	Methods that use *unlabeled* input data to discover data structure and learn efficient representations for data (e.g., clustering, dimensionality reduction)	Principle components analysis (PCA)	Uniform Manifold Approximation and Projection (UMAP)	Visualizing structure in gene expression levels and grouping asthma patients into distinct molecular clusters
Semi-supervised learning	Methods that use *both* unlabeled and labeled examples to learn functions better than possible in supervised setting alone	Self-training	Consistency regularization	Use of unlabeled cardiac magnetic resonance images alongside small dataset of labeled examples to detect hypertrophic cardiomyopathy
Reinforcement learning	Methods to teach an "agent" that iteratively interacts with its environment *how* to optimize a numerical reward	Optimal control	Deep reinforcement learning (e.g., AlphaGo Zero)	Selecting fluids and vasopressor dosing iteratively to manage sepsis for patients in the intensive care unit

output from input. The goal is to learn robust functions that work well with unseen data. If this setting is familiar, it is because clinical researchers often use well-known traditional statistical approaches like linear and logistic regression to achieve the same goal. For example, clinical risk scores, such as the American College of Cardiology (ACC)/American Heart Association (AHA) Atherosclerotic Cardiovascular Disease (ASCVD) Pooled Cohort Risk Equations or the Framingham Risk Score, are based on fitting models with paired input data (e.g., age, sex, LDL cholesterol, smoking history) and labeled output data (e.g., first occurrence of nonfatal myocardial infarction, coronary heart disease [CHD] death, or fatal or nonfatal stroke). Contemporary deep-learning methods can learn flexible representations of *raw* input data as opposed to relying on expert-identified features (Table 488-1). A contemporary clinical example of supervised machine learning with convolutional neural networks is the histopathological detection of lymph node metastases in breast cancer patients (Table 488-1).

The three remaining types of machine learning have not been as widely applied to clinical problems to date, but we believe this is likely to shift in coming years. These include unsupervised learning, semi-supervised learning, and reinforcement learning. Unsupervised learning, in contrast to supervised learning, encompasses methods that use *unlabeled* input data, where the goal is to discover the "structure" present in the data. A researcher may use unsupervised methods to determine whether or not the data lie on a low-dimensional "manifold" that is "embedded" in a higher-dimensional space. For example, a researcher may obtain gene-expression measurements from more than 20,000 protein-coding genes for a large group of asthma patients and then "project" each patient into a lower-dimensional space to visualize and understand structure present in the dataset, or may group asthma patients by similarity across all gene-expression values. Classical linear methods include principal component analysis (PCA) and contemporary nonlinear approaches include uniform manifold and approximation and projection (UMAP) (Table 488-1). Semi-supervised learning is a hybrid between supervised and unsupervised learning, with methods that use *both* labeled data and unlabeled data. These algorithms exploit the (often low-dimensional) structure of unlabeled data to learn better models than may be possible in a purely supervised setting where labeled data may be scarce. Finally, reinforcement learning is a distinct subfield of machine learning that focuses on optimizing the iterative decision-making of an "agent" that is equipped with a cumulative "reward" function, and thus must navigate a trade-off between exploration and exploitation of its environment, distinct from the other three subfields of machine learning where the entire learning signal (i.e., dataset) is presented at once. This approach to learning has been successful in teaching computers to play games at world-expert levels (e.g., Google's AlphaGo Zero).

MODERN MEDICAL MACHINE LEARNING

The modern machine-learning toolkit includes methods that differ extensively in their complexity and ability to learn directly from raw data (Table 488-2). "Traditional" statistical methods, such as linear and logistic regression, remain vital and often serve at minimum as

TABLE 488-2 Select Tools in the Modern Medical Machine-Learning Toolkit

METHOD	DEFINITION	NOTES
Linear and Logistic Regression	Models a linear relationship between predictors and either a continuous or binary outcome variable; "traditional" statistical modeling	Necessary baseline. In small carefully curated clinical datasets, these methods often perform on par with more sophisticated methods
Gradient-Boosted Trees	Ensemble of "decision trees" with parameters optimized to efficiently learn accurate nonlinear functions in supervised setting	Efficient to train and often performs well on machine-learning tasks with tabular data
Convolutional Neural Network (CNN)	Specialized deep-learning architecture with groups of neurons ("convolutional filters") that exploit structure	State-of-the-art in computer vision; de facto standard for medical imaging tasks (e.g., U-Net architecture for biomedical image segmentation)
Transformer Models	Deep-learning architecture designed for mapping input sequences to output sequences (e.g., text, speech)	Variants include Bi-directional Encoder Representations from Transformers (BERT), Generative Pre-trained Transformer 3 (GPT-3); state-of-the-art for tasks in natural language processing and machine translation
Generative Adversarial Network (GAN)	Deep-learning framework consisting of two networks that compete to better learn the "generative model" underlying training examples	Performs well on image-to-image translation tasks; can create realistic synthetic data, art, style transfer
Uniform Manifold Approximation and Projection (UMAP)	Dimensionality reduction technique to visualize and identify low-dimensional structure of high-dimensional dataset while preserving global structure	Nonlinear technique; many other techniques exist, e.g., principal component analysis (PCA), t-distributed stochastic neighbor embedding (t-SNE)
Transfer Learning	Family of approaches to adapt models trained for one task and apply to another task (across domains)	Useful for "jump-starting" a model for a new problem, e.g., many medical computer-vision models start with a network trained for a separate (often nonmedical) task such as ImageNet and may "fine-tune" for a particular medical application

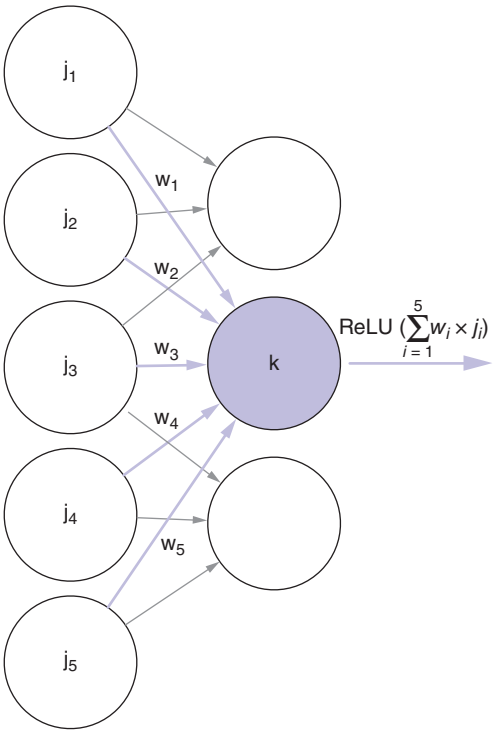

FIGURE 488-2 The artificial neuron, the building block of deep learning models. Neuron k accepts weighted input from neurons in the preceding layer and applies a function (e.g., ReLU(x) = max(0,x), the rectified linear function) to the weighted sum of inputs (often with a bias term, not shown). During training, the weights are iteratively refined to better fit the data.

useful and interpretable baselines, but often much more. Generalizations of these approaches as well as many other methods have been developed to learn complicated functions including highly nonlinear relationships. For example, models such as gradient-boosted trees (Table 488-2) often achieve excellent performance with tabular data that lack the spatial or temporal structure that newer deep-learning methods can exploit.

Modern deep-learning models can learn rich and flexible representations of raw clinical data. The building blocks of these models are simple artificial "neurons," often arranged into layers **(Fig. 488-2)**. Each neuron accepts input from neurons in a preceding layer, computes a weighted sum of these inputs, and applies a nonlinear function to the weighted sum (Fig. 488-2).

The values of the adjustable weights between neurons are *learned* during the training process. Neurons may be arranged into hierarchical layers that build an increasingly rich representation of input data. For example, convolutional neural networks (CNNs) are specialized architectures that combine groups of neurons with the mathematical operation of convolution ("convolutional filters") to exploit spatial structure (Table 488-2). Initial layers learn low-level features (e.g., edges) and then build to higher layers that learn motifs and objects, creating a powerful representation for discriminating between inputs using output labels **(Fig. 488-3)**.

Modern neural networks may have many millions and even billions of weight parameters. For example, the VGG-16 network by Simonyan and Zisserman, a path-breaking architecture and one of the top models in the ImageNet Large Scale Visual Recognition Challenge in 2014, had approximately 140 million parameters. The U-Net architecture by Ronneberger and colleagues, a convolutional neural network, is used frequently for biomedical image segmentation and other medical imaging tasks. Other deep-learning models have architectures tailored for distinct tasks and data types including sequence-to-sequence and Transformer models, designed for sequential data, including unstructured text notes from electronic health records (Table 488-2). Generative adversarial networks (GANs) feature an architecture with two co-trained competing ("adversarial") networks and exhibit what many would describe as artistic talent or creativity. Finally, many unsupervised dimensionality reduction techniques have recently been introduced to discover nonlinear structure including, for example, Uniform Manifold Approximation and Projection (UMAP), though linear (e.g., PCA) and nonlinear (e.g., t-SNE) alternatives exist as well (Table 488-2). In many deep-learning applications, it is important to note that practitioners often do not train networks tabula rasa but

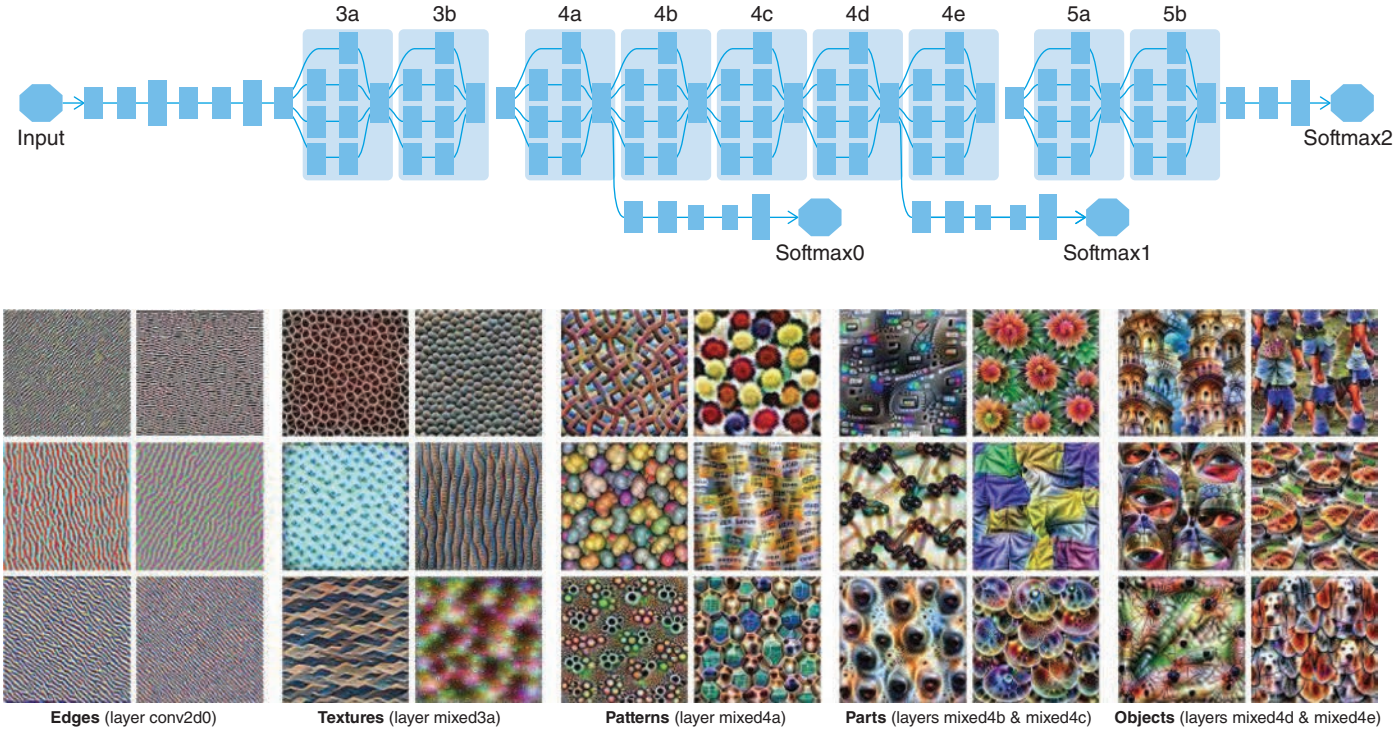

FIGURE 488-3 Deep-learning models learn rich hierarchical representations. Visualization of what a convolutional neural network "sees" as it is processing images of common objects from the ImageNet dataset. The initial layers learn low-level features like edges and the higher layers learn patterns and objects. *(Reproduced from distill.pub by C Olah et al: Feature visualization. TABLE 488-3 Practical Concepts for Training a Deep-Learning Model

CONCEPT	DEFINITION	EXAMPLES
Loss Function	Mathematical function that quantifies discrepancy between predicted label and true label	Cross-entropy, quadratic, 0–1
Back-propagation	Algorithm to compute the direction of the loss function with respect to changes in the adjustable weights ("gradient")	—
Graphics Processing Unit (GPU)	Specialized computer hardware to speed up the many matrix calculations involved in training a neural network	NVIDIA Tesla V100
Train-test Split	How data are divided to ensure fair estimates of model performance after training	70% training, 30% test
Area Under the Receiver Operating Characteristic Curve (AUC)	Common performance metric for evaluating binary classification models. 0.5 = random, 1.0 = perfect	—
Deep-Learning Framework	Computational framework for efficiently performing matrix (tensor) calculations for training deep-learning models	TensorFlow, PyTorch, Keras

instead benefit substantively from transfer learning (Table 488-2), where the weights may be initialized or "pretrained" from another task.

PRACTICAL CONCEPTS IN TRAINING A MODERN MACHINE-LEARNING MODEL

In this section, we provide a brief overview of practical concepts that emerge when training a modern machine-learning model to help readers understand the constraints and choices that confront machine-learning practitioners.

Often the first task is to define what a "good" prediction is by specifying a "loss function," which quantifies the error between a model's prediction and the true label **(Table 488-3)**. There are many choices for this function. Linear regression uses quadratic loss; other examples include the cross-entropy and 0–1 loss. Given a loss function, the stochastic gradient descent method coupled with the backpropagation algorithm quantifies how to alter the adjustable weights in the network to optimize the loss function iteratively as labeled examples are provided to the network, either one by one or in batches. The weights themselves are often initialized carefully and frequently transferred over from another task. Most machine-learning practitioners use specialized hardware called graphics processing units (GPUs) to perform these calculations. As with most computer hardware, GPUs range dramatically in performance and cost. Software frameworks like PyTorch and TensorFlow automate much of the otherwise-cumbersome training process, abstracting away in a dozen lines what might have previously taken a team of machine-learning engineers months to build. The machine-learning community places great emphasis on generalization through near-universal practices such as widely available benchmark datasets, and splitting training and testing data, with performance measures such as the area under the receiver operating curve (AUC) computed in held-out test data to improve estimates (Table 488-3).

APPLICATIONS OF MODERN MACHINE-LEARNING TO CLINICAL MEDICINE

Two major classes of applications have dominated recent machine-learning applications in medicine: computer vision and natural language processing. We review some of the recent applications below, highlighting the breadth of challenges across clinical specialties and some emerging new directions.

COMPUTER VISION

Medical computer-vision applications, particularly those employing convolutional neural networks, have dominated the medical machine-learning literature over the past decade. Convolutional neural networks are well suited to exploit the spatial structure in medical-imaging data and are able to learn detailed representations of input images, yielding systems that often perform on par with or better than expert physicians at select tasks. One of the most well-known medical computer-vision applications during the past decade was published in a paper by Gulshan and colleagues in the *Journal of the American Medical Association* (*JAMA*) in 2016. The authors trained a convolutional neural network using 128,175 ophthalmologist-labeled retinal fundus photographs to develop an automated diabetic retinopathy detection system, achieving performance on par with expert ophthalmologists, with an AUC of 0.99 in two separate validation datasets. In a separate study by De Fauw and colleagues, 14,884 three-dimensional retinal optical coherence tomography (OCT) scans were used to train a deep-learning model that could make referral suggestions and performed with an accuracy at or superior to eight clinical experts who graded the same scans, with an AUC in test data over 0.99 for urgent referral vs. other referrals. Some machine-learning applications in ophthalmology have already received approval from the U.S. Food and Drug Administration (FDA) including the IDx-DR "device" to classify more than mild diabetic retinopathy.

Outside of ophthalmology, computer-vision applications have been numerous across the many other specialties that rely on imaging data. For example, dermatologist-level classification of skin cancer was achieved in a study by Esteva and colleagues published in *Nature* during 2017. The authors trained a convolutional neural network to distinguish between keratinocyte carcinomas and benign seborrheic keratoses as well as between malignant melanomas and benign nevi. The authors concluded that the model performed at the level of the 21 board-certified dermatologists against which it was tested.

The uses of machine-learning models in radiology are numerous as well, with applications including the detection of pneumonia from chest x-rays, identification of pancreatic cancer from CT scans, and fast, automated segmentation of cardiac structures from cardiac MRI, as well as echocardiography.

Specialized deep-learning architectures such as the U-Net architecture by Ronneberger and colleagues have become especially popular in the medical computer-vision community. Architectures are often designed for specific imaging tasks (e.g., image segmentation) or specialized data types (e.g., three-dimensional images or videos). New frontiers of computer-vision research in medicine include semi-supervised learning approaches to take advantage of extensive unlabeled data available at hospitals, particularly given the practical difficulty and cost for an individual researcher to obtain large expert-labeled datasets.

NATURAL LANGUAGE PROCESSING

Like computer vision, natural language processing (NLP) has been transformed by modern machine-learning approaches, particularly deep learning. Deep-learning approaches include recurrent neural networks, newer sequence-to-sequence models, and the recently developed Transformer model (Table 488-2), which are well suited to exploit the structure of text and natural language in both supervised and unsupervised settings. These models have been successfully applied to analyze physician notes in the electronic health record, detect depression symptom severity from spoken language, and scribe patient-physician visits. For example, a study by Rajkomar and colleagues analyzed electronic health record data from 216,221 adult patients to predict in-hospital mortality, 30-day unplanned readmission, and discharge diagnoses amongst other outcomes, performing at high accuracy, with an AUC of 0.93–0.94 for predicting in-hospital mortality. It is important to note that much of the progress in medical natural language processing has stemmed from the widespread availability of datasets, for example the Medical Information Mart for Intensive Care (MIMIC) database.

Many specialized deep-learning architectures have been developed for natural language processing applications, including the analysis of electronic health record data, using both supervised (e.g., recurrent neural network) and unsupervised (e.g., variational autoencoder) approaches. Domain-specific language representation models have

been developed for the purpose of biomedical text mining, serving as a substrate for many downstream natural language processing tasks. These include, for example, the BioBERT model by Lee and colleagues, published in 2019, which adapts the Bi-directional Encoder Representations from Transformers (BERT) model (Table 488-2) for biomedical text mining.

OTHER APPLICATIONS

While medical computer vision and natural language processing tasks have been the focus of newer deep-learning models due to the extensive structure of imaging and text data, many other application classes exist. For example, cardiologist-level performance has been achieved in deep-learning approaches for detecting arrhythmias from ambulatory electrocardiograms, standing in contrast to the rule-based algorithms used traditionally to interpret electrocardiogram signals. In genomics, investigators have analyzed tumor genomes with machine-learning methods to better predict survival using both deep-learning and other machine-learning approaches. Machine-learning methods have also been used to characterize the deleteriousness of single-nucleotide variants in DNA. Many other applications of machine learning to new patient data streams are emerging, for example machine learning applied to wearables (e.g., smartwatches).

MACHINE LEARNING AND PRECISION MEDICINE: DEEPER REPRESENTATIONS OF PATIENT STATE

The modern machine-learning methods described in this chapter have much in common with the concept of *precision medicine*. As described in a report published by the National Academies of Sciences, Engineering, and Mathematics in 2011, precision medicine refers to "the ability to classify individuals into subpopulations that differ in their susceptibility to a particular disease, in the biology and/or prognosis of those diseases they may develop, or in their response to a specific treatment." This vision calls for the development of an "Information Commons," a patient-centric view of heterogeneous data streams (e.g., genome, environmental exposures, clinical signs and symptoms, transcriptome) that together paint a complete picture of an individual's health.

The machine-learning methods described in this chapter similarly operate on a heterogeneous and rich set of data to improve both the predictive abilities of physicians as well as the understanding of disease structure within and across data types. Modern machine-learning methods are especially well suited to improve the *representation* of a patient's clinical state, identity, and environmental context in order to improve individualized medical decision-making, learning data-driven "embeddings" of a patient's clinical state and identity in the process **(Fig. 488-4)**. Machine learning and precision medicine can thus be seen as aligned disciplines where flexible and powerful learning algorithms combine with rich and detailed data to augment clinical decision-making.

CONCLUSION

Modern machine learning offers a powerful set of techniques to learn feature representations directly from data, already performing on par with expert physicians on select tasks. If carefully trained and judiciously applied to key areas of clinician workflow, the representational power of new machine-learning methods makes them likely to touch every area of clinical practice.

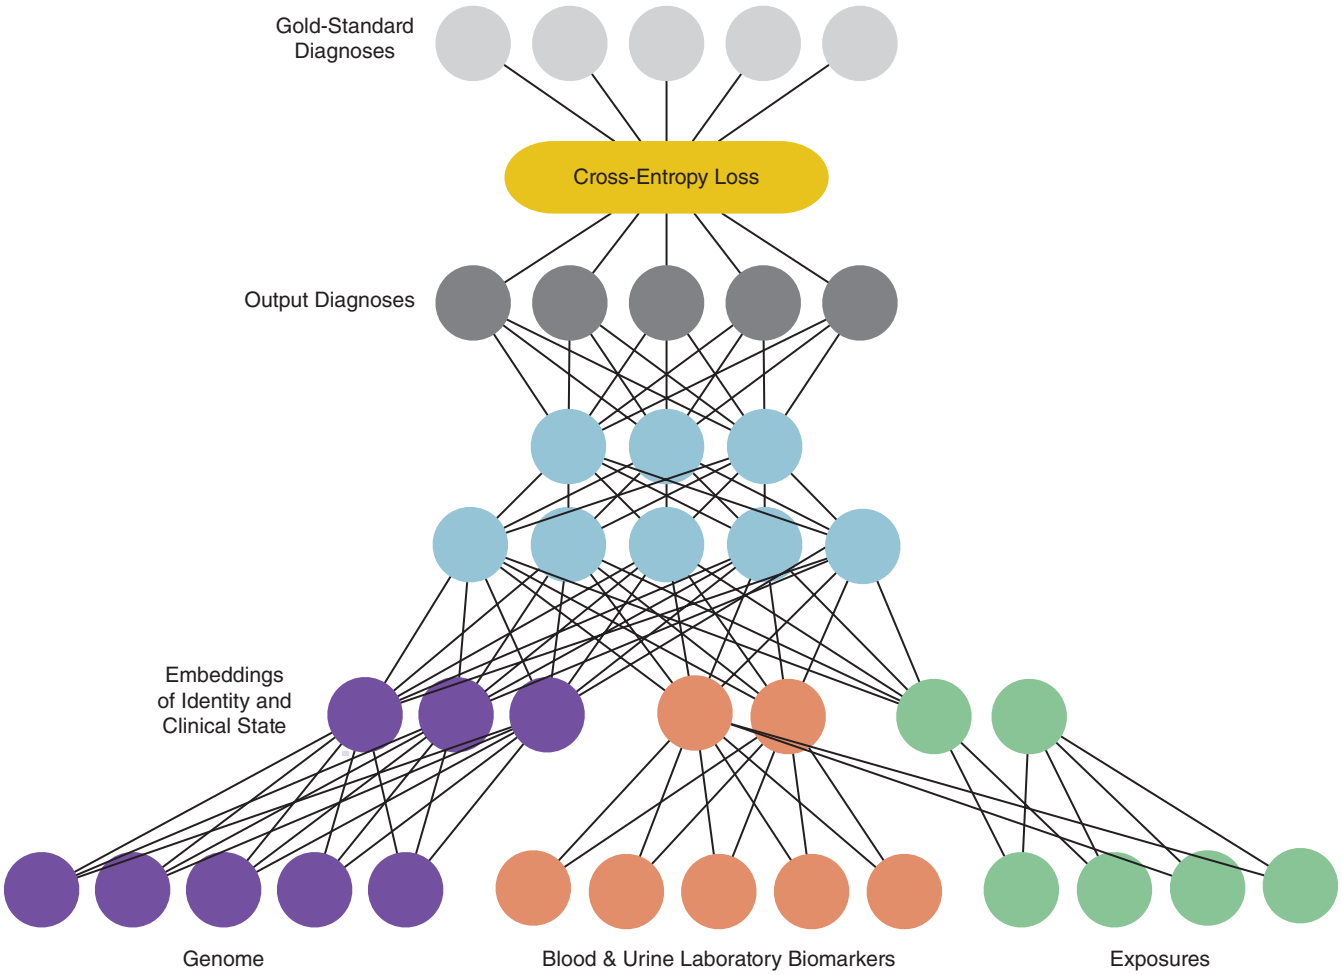

FIGURE 488-4 Machine learning and precision medicine: deeper representations of clinical state and identity. Diverse data streams (e.g., genome; blood and urine biomarkers, including triglycerides and LDL cholesterol; and exposures) are combined alongside labeled output diagnoses in a deep-learning model. In the process of training this model, a lower-dimensional representation of the high-dimensional input data ("embedding") is learned.

489 Metabolomics

Jared R. Mayers, Mathew G. Vander Heiden

Metabolism, loosely defined, represents the sum of all biochemical reactions involving small molecules with a molecular mass of ≤1000 Daltons within a given tissue, cell, or fluid. These small molecules are collectively referred to as *metabolites* and are involved in the biochemical processes used to create macromolecules and fulfill the evolving energy needs of a cell or organism. *Metabolomics*, then, represents the measurement of metabolites, either qualitatively or quantitatively, often as a way to gain insight into the metabolism of a cell, tissue, or organism. No one experimental approach can characterize metabolism in its entirety; metabolomics instead strives to measure a portion of the *metabolome*, which consists of all metabolites in a given biological sample at a given time.

A link to a time-specific context is common to all "-omics" techniques, but is particularly important in metabolomics. As metabolic processes are highly connected and interdependent, with individual metabolites often being involved in multiple pathways, levels of a specific metabolite can vary in response to an alteration in either the production or the consumption of that metabolite. Because significant changes in metabolite levels can occur over a very short time frame, the levels measured can be sensitive to perturbations either upstream or downstream of a metabolite in a pathway. This sensitivity can make measurement challenging, but it also makes metabolomics a powerful tool with which to assess either acute or chronic changes in cells or tissues. Indeed, the metabolome can be quite dynamic and reflective of the current condition of the material being assessed, as it ultimately represents an integration of outputs from the genome, epigenome, transcriptome, and proteome **(Fig. 489-1)**.

APPROACHES AND SAMPLING CONSIDERATIONS

UNTARGETED AND TARGETED METABOLOMICS

There are two distinct approaches to measuring metabolites in biological materials: untargeted and targeted metabolomics. These strategies differ in whether a predetermined subset of metabolites is intentionally sought in a sample, with the choice of approach dictated by the question under investigation. Regardless of the method utilized, it is important to recognize that no single metabolomics technique is comprehensive. Technical considerations heavily influence metabolite measurement, and no one method is able to capture the entire metabolome. In this respect, metabolomics contrasts with some other -omics techniques, like genomics or transcriptomics—i.e., in metabolomics, if something is not measured, its absence cannot necessarily be assumed.

Untargeted Metabolomics Untargeted metabolomics is the comprehensive analysis of all the measurable analytes in a sample, irrespective of their identity **(Fig. 489-2)**. Among the benefits of this approach is that it is agnostic in its measurement of the metabolome. Thus, it allows for the discovery of novel or unexpected molecules for further study. Coverage of the metabolome in an untargeted approach is influenced by the techniques used for sample preparation, metabolite separation prior to detection, and the inherent sensitivity and specificity of the analytical technique(s) employed (see "Metabolomics Technologies," below).

A major drawback of untargeted metabolomics is that molecules of interest can be measured with less confidence or missed entirely because this approach carries an inherent bias toward the detection of high-abundance molecules. Handling and interpretation of data also represent a major challenge, as each sample run generates large amounts of data whose analysis can be both complicated and time consuming. Identifying each metabolite measured requires database searching, and further experimental investigation is often needed to confirm the exact identity of a signal of interest. Finally, in most cases, this technique yields only relative metabolite quantification, thereby rendering it most useful for comparisons between biological samples.

Targeted Metabolomics Targeted metabolomics involves the measurement of a predefined group of chemically characterized metabolites—typically dictated by a hypothesis or predetermined platform—with the aim of covering a select portion of the metabolome. The metabolites measured represent only a subset of those that would be measured by an untargeted approach; thus a targeted approach generates a much smaller data set in which individual metabolites are detected with higher confidence (Fig. 489-2). Because the identity of each signal is known in advance, standards can be added to provide absolute quantification of each metabolite measured in the sample, although the use of targeted metabolomics to compare relative metabolite levels across samples is common. In addition, sample preparation and chromatographic separation before measurement can be optimized to improve detection of specific metabolites, enabling assessment of less abundant molecules.

The key downside of targeted metabolomics is that information is gained about only those metabolites targeted by the analytical method.

SAMPLING CONSIDERATIONS

Regardless of the approach used, it is critical to consider potential sources of error that can influence the conclusions drawn from a metabolomic analysis. Because of the dynamic nature of the metabolome, numerous biological confounders inherent to the samples themselves can affect levels of the metabolites measured. For this reason,

FIGURE 489-1 The metabolome is downstream of the outputs measured by other "-omics" technologies. Thus, the state of the metabolome can more closely reflect clinical and experimental phenotypes.

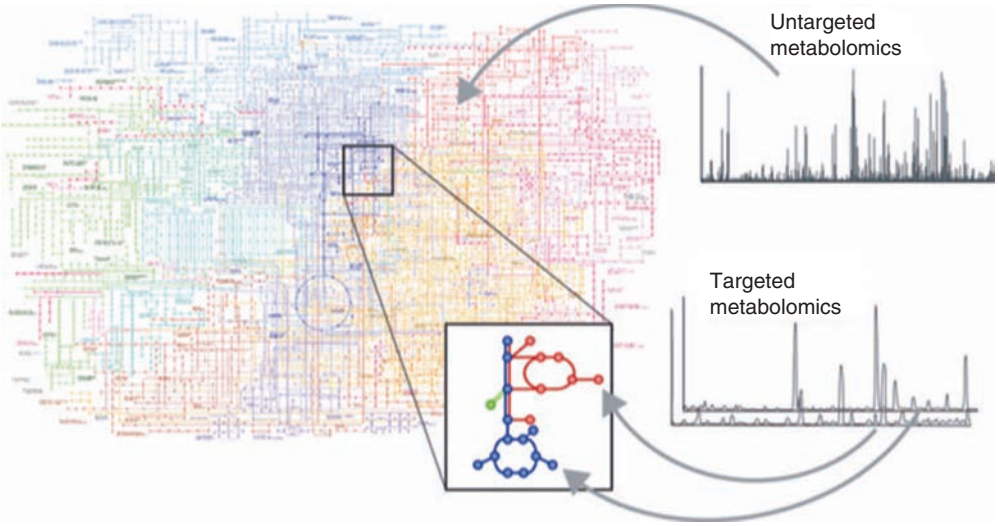

FIGURE 489-2 ***Untargeted*** **metabolomics strives to measure as much of the metabolome as possible within a given biological sample, whereas** ***targeted*** **metabolomics focuses on measuring a predetermined subset of the metabolome.** In untargeted metabolomics, a large number of signals corresponding to metabolites is generated, and further investigation is often necessary to assign a particular signal to a specific metabolite. Targeted metabolomics allows investigators to definitively measure signals that correspond to specific metabolites of interest.

the inclusion of controls or reference populations to account for these confounders can be critical for interpretation of the data. Established biological confounders for patient-derived material include age, sex, body mass index, fasting status and/or dietary differences, and comorbid conditions such as diabetes or smoking. For example, metabolites commonly altered with respect to aging are those in antioxidant and redox pathways as well as breakdown products of macromolecules. Sex differences influence a number of different metabolites, most prominently those involved in steroid and lipid metabolism. Perhaps it is not surprising that diet can also affect the metabolome, and fasting has been shown to impact almost every category of metabolite frequently measured in biological fluids.

Differences in sample handling and processing also influence metabolite measurements. Work using metabolomics to analyze material from large prospective cohort studies has shown that changes in metabolite levels introduced by sample handling can lead to falsely positive associations between specific metabolite changes and disease risk. Specific considerations include the large geographic area of distribution from which patients are drawn—e.g., a sample, such as blood, is collected locally and then exposed to variable conditions before being sent to a central lab for further processing. Moreover, because of the costs associated with obtaining and storing samples, often only one sample is available for each individual.

Time is a key variable in metabolite measurements, and efforts to assess the impact of sample handling and processing have led to improved analysis pipelines. For example, comparison of metabolites measured in samples undergoing immediate versus delayed processing can provide insight into those metabolites most affected by pre-processing storage under varying conditions. More specifically, because metabolism occurs on a very rapid time scale, some metabolite levels will continue to change after collection even if the sample is stored on ice. Therefore, metabolism is ideally halted or "quenched" immediately via rapid freezing or chemical extraction, but practical considerations involved in the collection of material from patients can sometimes make quenching impossible.

Sequential metabolomic analyses of the same type of biological material from a patient can explore how metabolite levels vary over time in individuals. It is interesting that, when measured, many metabolites are found to be relatively stable. However, the extensive variability exhibited by some metabolites indicates that findings involving those metabolites should be interpreted with caution.

Finally, the method of sample processing can affect which metabolites are extracted from the material and thus influence what is measured.

METABOLOMICS TECHNOLOGIES

Metabolomics relies heavily on the intersection of instrumentation, software, and statistical and computational approaches for measurement of metabolite levels and downstream data analysis. While the development of new and emerging techniques to assess the metabolome is ongoing, the current, clinically applicable approaches can be separated into two broad categories: nuclear magnetic resonance (NMR)–based approaches and chromatography/mass spectrometry (MS)–based approaches. Each of these two approaches has its own set of advantages and disadvantages.

NUCLEAR MAGNETIC RESONANCE

NMR is a technique that, at its core, exploits intrinsic magnetic properties of atomic nuclei to generate data. Nuclei with an odd total number of protons and neutrons (such as ^{1}H, ^{13}C, ^{15}N, and ^{31}P) have a non-zero spin, and this spin generates a magnetic field that can interact with externally applied electromagnetic fields. NMR places compounds into a magnetic field that induces the smaller magnetic fields to align with the larger one. Samples are then exposed to a perpendicular electromagnetic field; the frequency of electromagnetic radiation needed to flip the spin of a nucleus in the exact opposite direction represents the frequency at which an atom "resonates" and can be measured. The resonance frequency of a given atom is affected by adjacent atoms and is ultimately unique for a given arrangement of atoms (i.e., each metabolite). This distribution or "spectrum" of signals is measured and recorded in an NMR experiment.

With respect to clinical applications, the primary benefits of NMR-based approaches are that they are nondestructive and can be performed on living samples, such as patients, cells or tissues. They are also highly reproducible and require minimal sample preparation. Measurements are necessarily quantitative as the signal measured directly reflects concentration. These features ensure that multiple, comparable measurements can be made in a given sample either at a single point in time or across time. In addition, given that spins of different elements require sufficiently disparate resonance-inducing radio frequencies in order to be entirely distinguishable, multiple elements can be assessed in a sample; this feature allows multidimensional cross-referencing of signals such as hydrogen and carbon. In an untargeted analysis, these multidimensional data can then be used for definitive metabolite identification, with comparison of results to known databases where spectra for many metabolites in the human metabolome have been systematically recorded.

Despite all these benefits, the primary challenge of NMR-based approaches is a lack of sensitivity. Because the time required to detect

TABLE 489-1 Comparison of Nuclear Magnetic Resonance (NMR)–Based and Mass Spectrometry (MS)–Based Approaches to Metabolomic Analyses

FEATURE	NMR	MS
Reproducibility	High	Lower
Sensitivity	Low (low μM)	High (low nM)
Selectivity	Untargeted	Targeted >> untargeted
Sample preparation	Minimal	Complex
Sample measurement	Simple: single prep	Multiple preps
Metabolites per sample	50–200	>1000
Identification	Easy, using 1D or 2D databases	Complex; need standards and additional analyses
Quantitation	Inherently quantitative; intensity proportional to concentration	Requires standards because of varying ionization efficiency
Sample recovery	Easy, nondestructive	No
Living samples	Yes	No

a signal is proportional to concentration, assessment of less abundant species is impossible or impractical. For example, while a typical NMR-based metabolomics analysis will return data on up to a couple of hundred metabolites at concentrations of >1 μM, the MS-based approaches discussed below can distinguish more than 1000 metabolites at concentrations one to two orders of magnitude lower (Table 489-1).

CHROMATOGRAPHY/MASS SPECTROMETRY

A distinguishing feature of chromatography/MS–based approaches is that a multistep process that destroys the material is necessary to generate a sample for analysis. In addition, each step of the sample preparation process involves decisions that influence the metabolites measured at the time of analysis. In general, once a sample to be analyzed is prepared, that material is subjected to a combined chemical and temporal separation of compounds via chromatography, with the output delivered to a device for performance of mass-based detection (technically, measurement of a mass-to-charge [m/z] ratio)—i.e., mass spectrometry. Finally, data collected by the mass spectrometer are analyzed (Fig. 489-3).

Sample Preparation Although occasionally a part of NMR-based metabolite detection protocols, MS-based approaches almost uniformly require an initial sample-preparation phase called *extraction*. This technique destroys the original sample by partitioning metabolites into distinct immiscible phases, such as polar and nonpolar. These phases are then mechanically separated and processed further for analysis. Given the nature of this extraction process, it is critical to determine in advance the general class of metabolites to be measured. This information will help to determine the optimal extraction protocol for specific types of metabolites of interest and to shape further downstream decisions regarding the chromatography/MS technique that also influence metabolite detection. In addition, depending on the metabolites to be analyzed and the method of separation and/or analysis used, extracted samples sometimes are processed further in a preparative step called *derivatization*: extracted metabolites are chemically modified by the addition or substitution of distinct, known chemical moieties that facilitate separation or detection of types of metabolites. By changing the chemical properties of metabolites, derivatization may improve stability, solubility, or volatility or facilitate separation from closely related compounds, enhancing measurement of specific metabolites.

Chromatography Chromatography is a ubiquitous approach used in chemistry for the separation of complex mixtures. The mixture of interest in a mobile phase is passed over a stationary phase such that compounds in the mixture interact with the stationary phase and transit through that stationary phase at different speeds, allowing their consequent separation. Two general types of chromatography are typically used in metabolomics.

LIQUID CHROMATOGRAPHY Liquid chromatography–mass spectrometry (LC-MS) is the most commonly used approach in MS-based metabolomics. In this case, chromatography is characterized by a mobile phase that is a liquid and a stationary phase that is a solid. In liquid chromatography in particular, the choice of the solid and liquid phases can dramatically influence the types of compounds separated for input into the mass spectrometer. In general, LC-MS metabolomics is highly sensitive and versatile in allowing detection of a broad range of metabolites. A downside, however, is variability in exact separation timing, especially between different instruments; which metabolites are measured is impacted by the chromatography used and how well molecules are separated.

GAS CHROMATOGRAPHY Gas chromatography–mass spectrometry (GC-MS) involves chromatography in which the mobile phase is a gas. In contrast to LC-MS, GC-based approaches have a narrower range of applications because only volatile metabolites that enter a gaseous phase are separated. When combined with appropriate derivatization, GC-MS is a robust way to detect many organic acids, including amino acids, and molecules of low polarity, such as lipids. GC-MS is more reproducible than LC-MS across platforms and requires less expensive instrumentation and less specialized training, but it also typically measures a much more restricted range of metabolites in a sample than does LC-MS.

Mass Spectrometry Once the metabolites in a sample have been separated by chromatography, they are sent into the mass spectrometer for analysis and measurement. The first step in this stage of the process is to generate charged ions, as mass spectrometers measure compounds on the basis of their m/z ratio. Charge can be imparted through various techniques, although most commonly it is attained by either applying a high voltage to a sample or striking it with a laser.

A number of different types of mass spectrometer can be employed for metabolomics. Three of the most commonly available types are discussed below.

TANDEM MASS SPECTROMETRY Tandem MS relies on three sets of quadrupole magnets arranged in series. The power of this arrangement

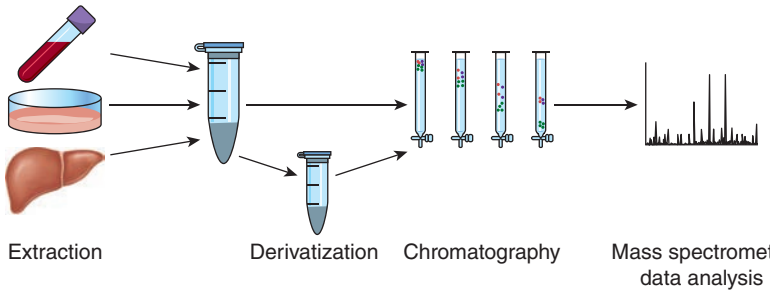

FIGURE 489-3 Metabolite measurement by chromatography/mass spectrometry–based approaches involves multiple steps, and decisions made at each step influence what is measured. First, metabolites are extracted from a biological sample in a manner that is destructive of the original sample. This process stops biochemical activity and creates metabolite samples that can be analyzed, sometimes after a chemical derivatization step that alters a subset of metabolites in a manner that facilitates their downstream analysis. Second, metabolites in the sample are separated via chromatography. Finally, the chromatographically separated compounds are analyzed by mass spectrometry. Each signal detected corresponds to a metabolite's characteristic mass per unit charge while the amplitude of that signal reflects the abundance.

lies in its specificity through two sequential mass analyses of the same starting compound. In the first quadrupole, the "parent" or full ion is measured before being bombarded by an inert gas in the second quadrupole; this process fragments the compound into characteristic smaller "daughter" ions. The third quadrupole then measures these daughter ions.

TIME-OF-FLIGHT MASS SPECTROMETRY While there are multiple types of time-of-flight (TOF) mass spectrometers, they all operate on similar principles. Most simply, lighter metabolites travel faster and heavier metabolites travel more slowly. TOF machines have high mass accuracy and sensitivity while also acquiring data quickly.

ION TRAP MASS SPECTROMETRY Ion trap mass spectrometers, of which the orbital trap is a subtype, offer perhaps the highest degree of flexibility when it comes to MS-based metabolomics. In general, these machines can select for a specific mass range of metabolites at multiple levels, first by filtering with a single quadrupole and then by trapping and accumulating metabolites of a particular mass or range of masses. This accumulation can be applied to low-abundance compounds, allowing increased sensitivity. It also allows repeated fragmentation of metabolites (called MS^n) to produce characteristic "daughter" ions, increasing the specificity of the analysis. Given this versatility coupled with high mass accuracy, the development of these machines is advancing rapidly; however, access to the latest versions can often be limited by cost.

CURRENT CLINICAL APPLICATIONS

Tests to assess small molecules are ubiquitous and well established throughout medicine. These include assays to measure select metabolites of known clinical relevance, such as glucose, lactate, and ammonia. Of note, many standard tests assess these metabolites one at a time; however, metabolomics can allow the assessment of many metabolites in a sample and provide more information on metabolic state at a given point in time. In some cases, metabolomics is used to detect molecules for which there is not a robust single analyte test or when multiple species measured in a sample might provide new information. Here we will focus specifically on several applications of metabolomics techniques in current clinical practice.

MAGNETIC RESONANCE SPECTROSCOPY

Magnetic resonance spectroscopy (MRS) is an adaptation of magnetic resonance imaging (MRI), a widely used technology in clinical practice. MRI, at its core, is essentially proton (^1H) NMR with the resulting data rendered spatially to generate an image. Recall that NMR is nondestructive and can be applied to living samples. MRS, then, is a capability built into almost every MRI machine. In practice, radiologists can focus in on specific volumes of interest within a patient's imaging and perform additional sequences to obtain an NMR spectrum in that space that can allow for the identification and quantification of specific metabolites in that space. With this approach, a number of different metabolites across diverse classes, including lipids, sugars, and amino acids, can be measured at a given time.

Extensive work has correlated different biological processes with altered levels and/or ratios of metabolites measured via MRS. One well-established application is in the diagnosis of brain masses. More specifically, *N*-acetylaspartate (NAA) is an amino acid derivative that is abundant in neurons, whereas choline is a metabolite whose level, as measured by MRS, correlates with cellularity and/or proliferation. Thus, an increase in the ratio of choline to NAA (and even loss of NAA signal entirely) correlates with cancer; tumors biologically are associated with the properties of increased cellularity from proliferation and the concurrent exclusion of normal neurons. A different process—for example, a brain abscess—does not result in increased choline levels (which instead may actually decrease), but does exclude neurons, resulting in an isolated NAA decrease. Metabolites such as lactate can also be helpful, depending on the clinical context, in providing insight into the metabolism of a tumor or identifying areas of early hypoxic brain injury after a stroke. Finally, among the several amino acids that can be measured, high levels of glutamine/glutamate can be helpful in a patient with altered mental status as changes in these amino acids are associated with hyperammonemia. (Glutamate serves as the central nervous system sink for ammonia, generating glutamine in the process.)

NEWBORN SCREENING PROGRAMS

Newborn screening programs are used to identify diseases within the first few days of life such that they can be treated or managed with early intervention. Among the classes of disease targeted by newborn screening programs are many inborn errors of metabolism, which often lead to changes in the levels of specific metabolites in blood or urine. One of the first newborn screening programs tested for phenylketonuria, which results from the inability to metabolize phenylalanine and causes high serum and urine levels of particular metabolites. Since that time, the panel used by programs throughout the United States and around the world has expanded dramatically. The general protocol is to collect a blood sample from infants in the first few days of life (often by heel prick on a piece of paper). These samples are sent to a central lab for analysis, which typically includes metabolomics measurements with targeted LC–tandem MS. Specific inborn errors of metabolism are suggested by abnormal levels of a given metabolite or set of metabolites.

METABOLITE MEASUREMENTS IN CHILDREN AND ADULTS

Outside the window of newborn screening, direct clinical measurement of metabolite levels is also used in pediatric and adult patients. In these cases, clinical samples such as serum, cerebrospinal fluid, or urine are typically subjected to targeted LC–tandem MS to measure metabolites such as amino acids, acylcarnitines, and fatty acids. These measurements can help diagnose milder cases of inborn errors of metabolism that may have been missed by newborn screening. They can also help identify secondary metabolic defects, such as those that are related to nutritional deficiencies or are acquired in the setting of additional pathology. For example, these measurements are useful in determining the etiology of noncirrhotic hyperammonemia exposed by a catabolic stressor such as sepsis in a patient with a previously unknown subclinical or acquired urea-cycle defect.

MS-based metabolomics is used by various athletic organizations for detection of metabolites associated with banned substances and by the pharmaceutical industry for assessment of levels of pharmaceuticals and their metabolites in both blood and tissues. Such analyses can provide key pharmacokinetic information to guide drug dosing and illuminate toxicology. These approaches can also be useful in clinical practice. For example, chronic pain and its management remain a challenge, and the sequelae of opiate/opioid use and abuse are of concern to many providers, their patients, and their patients' families. Therefore, many electronic medical records systems strive to ensure appropriate and consistent patient access to pain medications, while providers may need a means to ensure that patients are adhering to their prescribed regimens. One way to monitor drug use is to perform targeted LC–tandem MS for detection of specific drug metabolites in patients' urine. This approach is more sensitive than first-generation immunoassays and can detect a range of metabolites associated with other drugs beyond the one prescribed. Given that the first-generation immunoassays also often rely on confirmatory MS testing, upfront metabolomics reduces lab turnaround time and may also reduce costs by limiting multiple tests on the same sample.

EMERGING AND EXPERIMENTAL CLINICAL APPLICATIONS

The current clinical applications of metabolomics are largely limited to the indications described above. However, many ongoing efforts are aimed at expanding the use of metabolomics for detection of biomarkers that can help with disease diagnosis or prognostication.

METABOLITES AS BIOMARKERS OF DISEASE

There has been increasing work in prospective human cohort studies on the use of metabolomics, primarily MS-based approaches, to empirically identify small groups of metabolites whose altered levels are

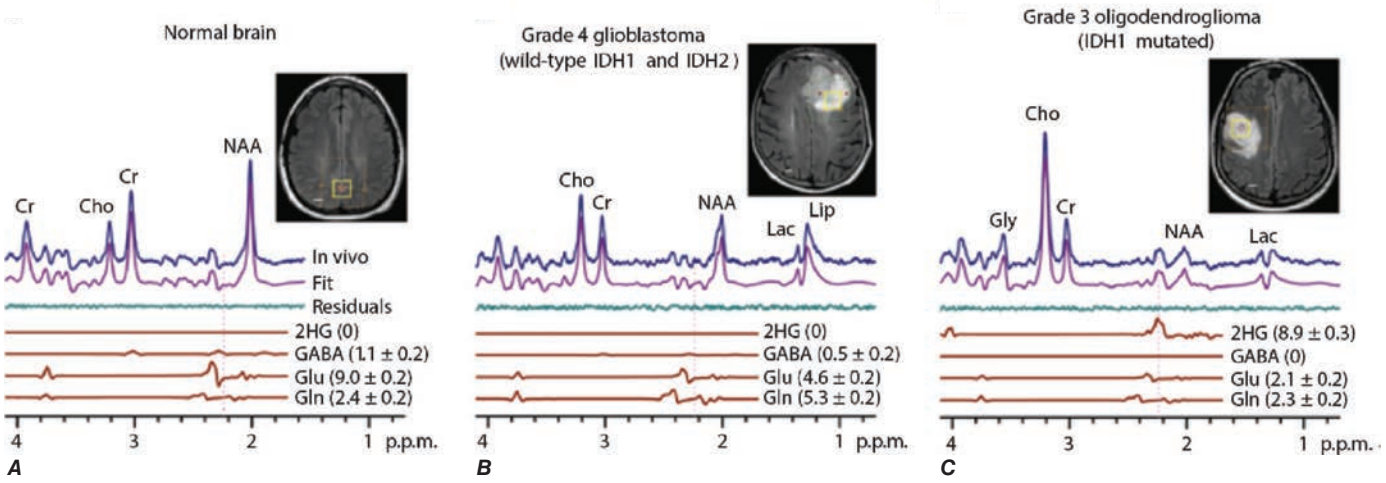

FIGURE 489-4 In vivo ^{1}H spectra and analysis demonstrating 2HG detection in IDH mutant brain tumors. ***A–C*** In vivo spectra from normal brain (***A***) and tumors (***B–C***), are shown. Components of 2HG, GABA, gluamate and glutamine are displayed. Measurement location indicated by yellow box (voxel). 2HG is seen only in mutant IDH brain tumors, but not normal brain or wildtype tumors. Shown in brackets is the estimated metabolite concentration (mM) ± s.d. Cho, choline; Cr, creatine; Glu, glutamate; Gln, glutamine; Gly, glycine; Lac, lactate; Lip, lipids. Scale bars, 1 cm. *(Reproduced with permission from Choi et al: 2012).*

associated with the development or progression of disease. Efforts to characterize these "metabolic signatures" have been focused primarily on common, multifactorial diseases such as diabetes, cardiovascular disease, and various cancers that are well represented in large prospective cohort studies. These studies have, for example, identified altered levels of amino acids that are associated with a future diagnosis of diabetes or pancreatic cancer.

Additional efforts have been made to assess the metabolome in patient samples at the time of an acute presentation. Because altered metabolite levels can be associated with a specific clinical diagnosis and/or outcome, the idea is to identify a metabolite signature that facilitates diagnosis or provides prognostic information. This approach has been studied, for example, in the context of sepsis and septic shock, in which blood lactate levels are assessed in combination with the use of clinical tools such as the Acute Physiology and Chronic Health Evaluation (APACHE II) or the Sequential Organ Failure Assessment Score (SOFA).

One key limitation in all of these studies is that researchers are primarily assessing correlations between blood plasma metabolite levels and complex, multisystem diseases. It is often difficult to obtain a biological understanding of the mechanisms driving these changes or, even more simply, the primary tissue source(s) of these alterations from human data alone, without further experimentation in model systems.

REFINING DIAGNOSIS AND PREDICTION OF DRUG SUSCEPTIBILITY

In contrast to the above-described use of metabolomics-based approaches in multifactorial diseases, the application of these approaches in some specific contexts can yield an immediate diagnosis and suggest actionable therapeutic interventions. One specific example in oncology involves an understanding of the pathogenesis of oncogenic mutations in the metabolic enzyme isocitrate dehydrogenase (IDH) isoforms 1 and 2. The normal function of these enzymes is to interconvert isocitrate and α-ketoglutarate; however, cancer-specific point mutations in these enzymes alter the enzymes' function in a manner conferring neomorphic activity that converts isocitrate into 2-hydroxyglutarate (2-HG). 2-HG is a metabolite that is typically present only at very low levels in cells, but when mutant IDH protein is present, 2-HG is produced and accumulates to high levels. Elevation of 2-HG can promote changes that directly contribute to malignancy; IDH mutations and 2-HG accumulation are found in several human cancers, including specific clinical subsets of acute myeloid leukemia and glioma. Given the unique and specific accumulation of 2-HG in these mutant tumors, detection of this metabolite by LC-MS and NMR-based approaches has been studied both for diagnostic purposes and as a means of assessing drug response. For example, researchers have applied MRS-based approaches to assess the accumulation of 2-HG in gliomas, as this finding can noninvasively identify patients with an IDH-mutant subset of this cancer **(Fig. 489-4)**. This diagnosis provides prognostic information and, in the future, may help direct therapeutic options. In principle, metabolomics may identify other disease biomarkers to aid with diagnosis or therapy assessment in a similar way.

PHARMACOMETABOLOMICS

The previous example positions metabolomics as a possible mechanism for achieving a more personalized approach to medicine. The emerging field of pharmacometabolomics aims to take personalization further by making this approach more widely applicable across drugs and disease states. The general workflow is to take a sample population and perform baseline metabolomics studies on blood from its members. The individuals then receive a given drug with subsequent blood-based measurement of drug metabolites to gain pharmacokinetics (PK) and pharmacodynamics (PD) information. These PK and PD data are then correlated with baseline metabolomic profiling, with the goal of generating a predictive model for individual PK and PD responses based on a naïve patient's metabolomic profile. Correlation with post-treatment metabolomics is also used to provide insight into how expected responses to therapy could be monitored. Ideally, this approach would allow clinicians to take a baseline set of measurements and then—a priori—choose a specific dose of a specific drug to produce the desired effect in that specific patient. Monitoring of the expected metabolite changes in response to the drug could also be used to ensure therapeutic efficacy. If successful, this method could limit both prolonged titration of medications and medication switching, dramatically shortening and simplifying the current approach to medical therapy.

EMERGING TECHNOLOGIES

While efforts to improve the existing capabilities discussed above are ongoing, innovations in instrumentation and computation are allowing collection of metabolite information that previously was not possible.

MASS SPECTROMETRY IMAGING

Most clinical metabolomics relies on analysis of bulk material, but in an individual patient there are areas of normal and diseased tissue, and understanding the differences in metabolism in these areas requires both spatially sensitive resolution (imaging) and interrogation (metabolomics). While MRS can perform some of these functions, it is limited to macroscopic imaging (MRI) and relatively insensitive metabolomics approaches (NMR). In contrast, MS-based approaches, while more sensitive, by their nature rely on specimen destruction and homogenization. The premise of mass spectrometry imaging (MSI) is to overcome these limitations of MRS and mass spectrometry. MSI combines histologic evaluation of tissue with MS-based approaches to assess spatial differences in metabolism. MSI as a technique has been

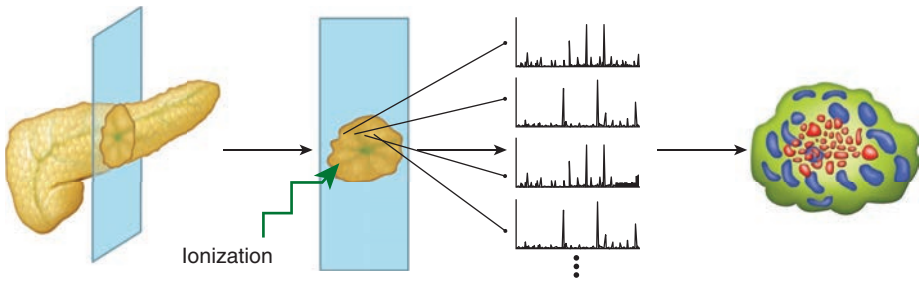

FIGURE 489-5 Mass spectrometry imaging provides spatial information around metabolites in tissues. Tissue is mounted onto a slide, and a laser or another method is used to ionize metabolites in a discreet section of the tissue for detection by mass spectrometry. The process is repeated as the laser scans across the tissue, generating an "image" based on the levels of a metabolite detected at each point in the tissue section.

most highly refined in the neurosciences and can provide subcellular resolution. In general, thin slices of tissue are mounted on a slide, and metabolomics is performed at defined points across the slide, yielding spatial information on where in the tissue section metabolites are measured. One specific approach utilizes matrix-assisted laser desorption/ionization (MALDI) coupled to MS. In MALDI, tissues are coated with a special matrix and the MALDI laser scans point-by-point across a tissue slice, ionizing the metabolites at each location for analysis by a mass spectrometer. These data can then be referenced back to an image of the original tissue slice **(Fig. 489-5)**. This approach is being tested for defining brain tumor margins in real time during resection and thereby providing insight into boundaries between normal and abnormal tissues.

IMPROVING UNTARGETED METABOLOMICS

Identifying unknown signals in an untargeted metabolomics analysis remains one of the central challenges in the field. As discussed above, NMR can definitively identify unknown signals but lags significantly behind MS-based approaches in its sensitivity and therefore in the number of signals it can detect. To leverage the sensitivity of MS-based detection and overcome the challenge of metabolite identification, researchers are applying computational techniques, using network-style analyses to streamline the process. The general approach is to combine information from known biological perturbations (e.g., changes in experimental conditions or disease states), empirical mass and structural information from MS analysis, and correlations with known metabolites/pathways to place unknown metabolites within existing metabolic networks.

SUMMARY

Metabolomics is part of a growing list of "-omics" techniques that have emerged over recent decades. Despite its immaturity relative to genomics, the power of metabolomics comes from being directly connected to phenotype and being very sensitive in measuring perturbations within a system or a patient. While the clinical applications of metabolomics are currently limited to specific indications, researchers are pushing to expand these technologies toward broader use in medicine. If these methods are to be used appropriately, clinicians need to be aware of established biological and practical confounders. Similarly, a basic knowledge of the technologies in use and their inherent limitations is critical. With time and further technical development, metabolomics could become a routine part of the clinical armamentarium for diagnosis, monitoring, and treatment of disease.

490 Circulating Nucleic Acids as Liquid Biopsies and Noninvasive Disease Biomarkers

Ash A. Alizadeh, Kiran K. Khush, Yair J. Blumenfeld

While this chapter is focused on the modern use of liquid biopsies and their applications in the context of malignancies, transplantation, and noninvasive prenatal testing, it is worth considering that the history of liquid biopsies dates back many centuries. Indeed, as early as the fourth century B.C., Hippocrates is noted to have studied body fluids and humors to diagnose various maladies in his patients. By the mid-seventeenth century, the analysis of bodily fluids (especially urine) increasingly became a cornerstone of European medicine. However, arguably, the most important use of bodily fluids as liquid biopsies currently involves key clinical applications in oncology, solid organ transplantation, and prenatal diagnosis **(Fig. 490-1)**. Below, we discuss these applications of liquid biopsies in the context of modern medical management of patients with risk of cancer and tumor progression, posttransplantation outcomes, and obstetric management.

CELL-FREE DNA IN ONCOLOGY

Major advances in the twenty-first century in cancer biology have helped transform oncology, particularly with the advent of personalized cancer therapies, which are typically selected using molecular biomarkers to identify tumor-specific vulnerabilities. However, because tumor heterogeneity remains a major obstacle to cancer monitoring and treatment, better approaches are needed to define clinically actionable targets and to facilitate the individualized therapies that embody precision medicine. While much can be learned from studying tumor biopsies directly, such as molecular profiling that informs

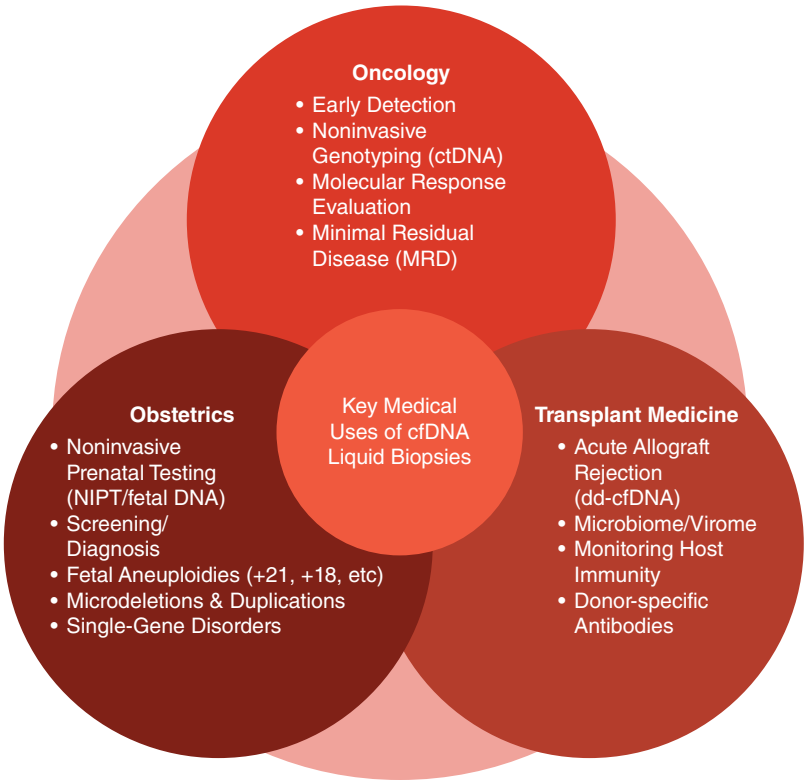

FIGURE 490-1 Key medical applications of liquid biopsies employing cell-free DNA (cfDNA), with specific focus on oncology, transplantation, and obstetrics. ctDNA, circulating tumor DNA; dd-cfDNA, donor-derived cfDNA; NIPT, noninvasive prenatal testing.

diagnosis and monitoring of pathologic response, these are invasive clinical procedures. In addition, tumor biopsies may not yield enough material for analysis and can be risky to the patient. Therefore, an approach to analyze cancer less invasively, such as from a blood sample, serves as a potentially attractive alternative in the clinical evaluation of patients with cancer.

Tumors are well known to release analytes into body fluids, including the peripheral blood circulation, and the diagnostic use of such analytes has often been referred to as liquid biopsies (Fig. 490-2). For hematologic malignancies such as leukemias, the direct examination of circulating hematopoietic elements is a cornerstone for diagnosis, response, assessment, and disease monitoring. Indeed, molecular tools allowed the specific detection of lymphoma B cells in the blood circulation using in situ hybridization in the mid-1980s, even before the advent of polymerase chain reaction for more sensitive detection. However, even when considering hematologic neoplasms such as lymphomas, many do not circulate in large numbers in the blood. Indeed, the dominant anatomic distribution of most human cancers results in the absence of detectable circulating tumor cells as evidence for minimal residual disease (MRD) in the cellular compartment of the blood.

Aside from extravasated tumor cells circulating in the bloodstream as circulating tumor cells (CTCs), liquid biopsy methods using peripheral blood also include membrane-bound vesicles released by tumor cells called exosomes, as well as non–membrane-bound derivatives such as cell-free DNA (cfDNA) and cell-free RNA (cfRNA), which are released by apoptotic or necrotic tumor cells. Although the most common source of liquid biopsy is the peripheral blood, various bodily fluids have been used for specific liquid biopsy applications to interrogate proximally associated anatomic compartments, whether using urine, feces, pleural fluid, peritoneal fluid, bronchoalveolar lavage fluid, saliva, or cerebrospinal fluid. For example, urinary cfDNA has shown promise for noninvasive detection of genitourinary tumors including bladder carcinomas, and colorectal cancer screening can be done using multianalyte assays leveraging fecal DNA.

Among the most intensively studied tumor-derived biomarkers is circulating tumor DNA in the blood plasma, as a subset of cfDNA. cfDNA in the blood was first described in 1948 by Mandel and Metais,

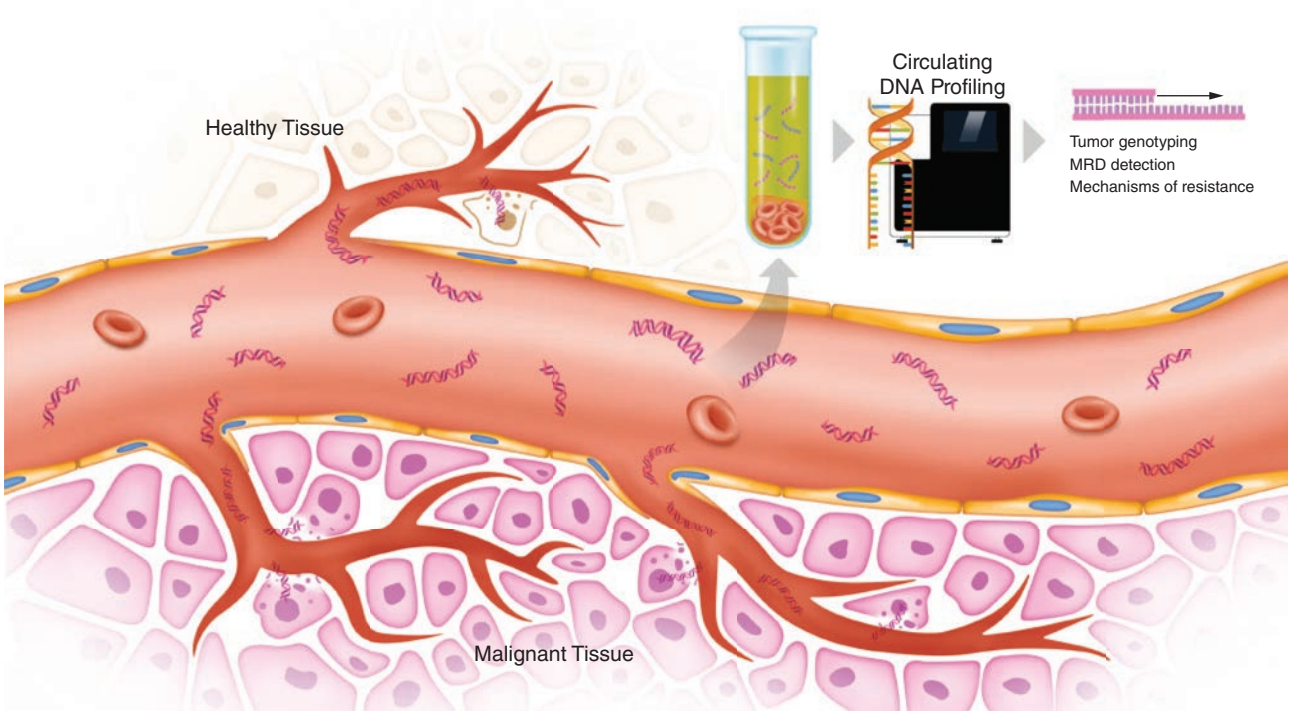

FIGURE 490-2 Cell-free DNA (cfDNA) is released both from healthy and malignant tissues. Tumors shed circulating tumor DNA (ctDNA), a minor fraction of all circulating cfDNA. Molecular profiling of cfDNA enables cancer detection and monitoring applications. MRD, minimal residual disease. *(Source: Adapted from BJ Sworder et al: Hematological Oncology, 39, 2021. https://doi.org/10.1002/hon.6_2879.)*

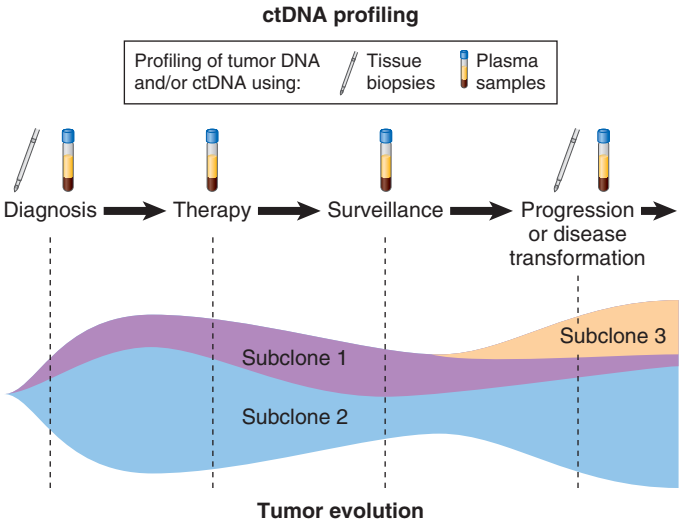

FIGURE 490-3 Framework for noninvasive identification of cancer risk groups. Schematic illustrating the application of ctDNA profiling for the identification of adverse risk at different disease milestones. A cancer patient is imagined as experiencing these disease milestones over time, depicted as an arrow progressing from left to right. During this temporal sequence, ctDNA can inform risk at diagnosis, during therapy, in surveillance of disease, and at progression or disease transformation. At diagnosis, profiling of tumor DNA obtained from either tissue biopsies (indicated by a scalpel) or plasma (depicted as blood collection tubes) allows for the identification of patients with high tumor burden and disease subtypes defined by specific genomic aberrations. Assessment of ctDNA during and after treatment facilitates the detection of both emerging resistance mutations and minimal residual disease (MRD) before progression, with potential for noninvasive prediction of relapse and treatment resistance. Tumor evolution in an anecdotal patient is illustrated, showing tumor response and clonal evolution over the course of the disease (detectable subclones at diagnosis are shown in blue/gray; an emergent subclone after therapy is shown in red). The profiling of tumor DNA and ctDNA at each milestone is shown by a double-stranded DNA molecule. *(Adapted from F Scherer et al: Distinct biological subtypes and patterns of genome evolution in lymphoma revealed by circulating tumor DNA. Sci Transl Med 8.364:364ra155-364ra155, 2016.)*

but it was not for another four decades that tumor-derived DNA was first observed in the plasma of cancer patients. Interestingly, cfDNA is naturally fragmented with lengths that correlate with DNA wrapped around individual nucleosomes. Since both healthy cells and cancer cells release their DNA into the circulation, a major challenge is attaining enough sensitivity to identify and quantify tumor-derived circulating DNA (circulating tumor DNA [ctDNA]) against a potentially large background of normal constitutional or germline DNA, the majority of which derives from hematopoietic sources. Methods based on next-generation sequencing offer a way to achieve this. Over the past two decades, ctDNA has been established as an important biomarker for studying tumor biology and for detection of cancers. Here, we summarize key applications of ctDNA in the context of early cancer detection, noninvasive tumor genotyping and classification, molecular response during therapy, and MRD after definitive therapy **(Fig. 490-3)**.

EARLY CANCER DETECTION

For several common cancer types including carcinomas of the lung, colorectal tract, and breast, early cancer detection via screening can improve outcomes for adults with established risk factors. However, such screening can pose significant risks and associated expenses that limit broad adoption. For example, while annual radiologic screening by low-dose computed tomography is recommended to screen for lung cancers in high-risk populations, implementation has been complicated by a high false discovery rate (~90%) and low compliance. Separately, distinct tumor types currently require unique corresponding screening tests. Finally, most existing cancer screening modalities have not fully integrated some of the key insights gained through molecular profiling of cancer genomes. Therefore, there is an unmet need for new methods for the early detection of cancers. Analysis of ctDNA is a promising approach that could facilitate blood-based screening. In this context, several efforts to leverage ctDNA for early detection are emerging, including approaches focused on individual cancer types, multianalyte testing combining ctDNA with other biomarkers including proteins, and broader multicancer early detection (MCED) assays leveraging mutations, tissue-specific methylation, cfDNA fragmentation profiles, and other features.

Despite much excitement about their promise, most such cancer detection efforts are relatively early in their development. As of 2021, no screening studies have prospectively applied liquid biopsies as interventions in randomized studies, with survival outcomes as clinical endpoints. Indeed, no studies performed to date have demonstrated a survival advantage of early detection using liquid biopsies in randomized trials, and this remains a key hurdle limiting widespread clinical adoption of these tests. With these limitations in mind, future prospective studies with substantially longer-term follow-up are needed to better establish the sensitivity and specificity of MCED tests for early cancer detection, when considering the common cancer types most amenable to localized interventions with curative intent. Separately, because early cancer detection may not improve cancer-specific survival, studies will also be required to determine if these tests can yield more true positives than false positives, especially because false-positive results can generate a substantial number of expensive secondary invasive procedures.

NONINVASIVE TUMOR GENOTYPING

Molecular subgroups defined by activating mutations in key oncogenic drivers are the basis for many targeted therapies in oncology across diverse cancers. For example, targetable mutations in the *EGFR* gene are the most common oncogenic driver in non-small-lung cancer (NSCLC), and the presence of *EGFR* mutations in NSCLC tumor biopsies is strongly correlated with a positive response to small-molecule EGFR tyrosine kinase inhibitors (TKIs). While tissue-based determination of tumor genotype is still considered by many to represent the gold standard for diagnostic purposes, liquid biopsies have demonstrated very high positive predictive value for noninvasively determining tumor genotype in the setting of advanced malignancies. Indeed, several liquid biopsy assays have been approved by the U.S. Food and Drug Administration (FDA) for companion diagnostic use to identify mutations associated with response to targeted therapies in diverse tumor types. Currently, several comprehensive genomic profiling liquid biopsy assays targeting >50 frequently mutated genes are currently available as FDA-approved noninvasive tumor genotyping tests for various solid tumors. For example, liquid biopsy testing using the Guardant360 test (Guardant Health, Inc.) in patients with NSCLC can be performed to identify *EGFR* mutations associated with response to osimertinib or amivantamab or to identify *KRAS* mutations associated with sotorasib response. Similarly, liquid biopsy testing using the FoundationOne Liquid CDx test (Foundation Medicine, Inc.) can be performed to identify *BRCA1/2* gene mutations associated with rucaparib response in ovarian cancer, *ALK* rearrangements associated with alectinib response in NSCLC, *PIK3CA* mutations associated with alpelisib response in breast cancer, and *BRCA1, BRCA2,* and *ATM* mutations associated with olaparib response in metastatic castration-resistant prostate cancer.

Of note, such assays have largely been developed for noninvasive tumor genotyping in the setting of advanced malignancies and are not well suited in the context of early-stage tumors. Indeed, a recent analysis by the Sequencing Quality Control Phase 2 (SEQC2) Project Working Group led by the FDA found that ctDNA detection was less reliable below a circulating variant allele fraction of 0.5% for mutations of interest. Accordingly, the currently available assays designed for the primary purpose of noninvasive genotyping in advanced disease are generally not optimal for detection of MRD because the residual ctDNA allele fractions after definitive treatment of localized solid cancers are typically much lower than 0.5%. Furthermore, even prior to treatment of advanced cancers and especially in the context of low metastatic tumor burden, the modest sensitivity of such liquid biopsy tests currently requires that if specific lesions of interest are not initially detected in the blood, a tumor biopsy is still needed to determine if the specific mutations and alterations are present, as this could inform therapy selection.

BIOLOGIC CONSIDERATIONS

In addition to the somatic mutations found in cfDNA that originate from tumor cells, somatic mutations arising in nontumor tissues can pose as a source of biologic "background." Such mutations can confound the use of ctDNA for cancer detection and monitoring. Hematopoietic stem cells can acquire mutations through a process called age-related clonal hematopoiesis (CH), resulting in variants that can be found in both cfDNA and circulating peripheral blood leukocytes. When considering peripheral blood cells in patients who do not otherwise meet criteria for a leukemia diagnosis, identification of mutations in ~20 genes canonically associated with hematologic neoplasms (and exceeding 2% in allelic fraction) is termed *clonal hematopoiesis of indeterminate potential* (CHIP). CHIP has been identified as a risk factor for cardiovascular disease and hematologic neoplasms and is also relevant for liquid biopsies **(Fig. 490-4)**. For example, because most cfDNA derives from hematopoietic sources, CH represents a major contributor to biologic mutational background for various applications of liquid biopsies across cancers. Importantly, the prevalence of CH variants increases with patient age, larger gene panels, and more sensitive testing, with prevalence approaching 100% in adults >60 years old.

Indeed, in liquid biopsy applications for noninvasively identifying somatic alterations using cfDNA, CH represents the dominant biologic source of false-positive findings, even if this can vary as a function of the specific genes or lesions being considered. While CHIP disproportionately affects genes such as *DNMT3A*, *TET2*, *ASXL1*, and *JAK2*, which are associated with myeloid cell fitness, population sequencing studies have shown that many more genes in the genome can be affected by somatic mutations arising during CH in aging adults. For example, independent liquid biopsy studies have identified that 15–41% of cfDNA mutations in the *TP53* gene can be attributable to CH because these same lesions were found in matched blood leukocytes but not in biopsied tumor tissues.

Accordingly, direct genotyping of peripheral blood leukocytes can be very helpful to avoid such cfDNA mutations arising from CH, which can potentially be false-positive results masquerading as ctDNA. However, studies suggest that ~10% of mutations found in cfDNA of otherwise healthy adults may not be found in matched leukocytes. This suggests other noncirculating sources of such cfDNA mutations, including CH arising in noncirculating hematopoietic precursors in tissues such as the bone marrow or from clonal proliferations of nonmalignant, nonhematopoietic cell types. Indeed, recurrent somatic mutations in genes such as *KRAS*, *MED12*, *BRAF*, and others can be present in diverse nonmalignant cell types. These mutations (and others) can arise in a range of epithelial, endothelial, and stromal constituents of vascular malformations, endometrial leiomyomas, melanocytic nevi, and other nonmalignant proliferations. As detailed below, incorporating sequencing of tumor tissue to initially identify somatic mutations that are later monitored in plasma samples can help to guard against these nonmalignant sources of biologic background.

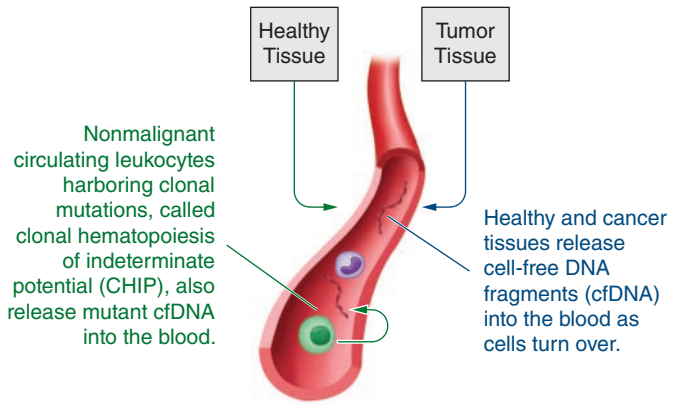

FIGURE 490-4 Contribution of clonal hematopoiesis of indeterminate potential (CHIP) to cell-free DNA, as relevant for tumor genotyping and monitoring using circulating tumor DNA. *(Source: Adapted from J Boegeholz et al: Hematological Oncology 39, 2021. https://doi.org/10.1002/hon.23_2879.)*

PRETREATMENT TUMOR BURDEN

In patients with an established cancer diagnosis, liquid biopsies can be useful as a noninvasive means of tumor genotyping using plasma, in a manner that informs therapy selection in such scenarios as described above. Aside from this use, quantitative assessments of tumor burden in the plasma prior to therapy can also provide valuable information via liquid biopsies. For example, pretreatment ctDNA levels have been shown to have significant associations with established measures of tumor burden and disease risk including stage, metabolic tumor volume, and serum protein markers such as lactate dehydrogenase in lymphomas, CA19-9 levels in pancreatic cancers, and carcinoembryonic antigen levels in colorectal cancers, among others. Importantly, in many of these scenarios and in other cancers such as NSCLC where noninvasive tumor biomarkers are not available, pretreatment ctDNA levels have been shown to have strong prognostic value for treatment failure and disease progression, providing an independently prognostic measure of risk. Indeed, such pretreatment ctDNA levels can be used to noninvasively measure tumor burden poorly captured by other indices that can lead to biases in clinical trials, including the diagnosis to treatment interval in lymphomas. Accordingly, pretreatment ctDNA levels may be used to prevent selection bias in prospective clinical trials. However, while such independent prognostic value of liquid biopsies has been validated for several tumors (e.g., using CTC levels in breast cancers), randomized trials demonstrating the clinical utility of these measurements for predicting therapeutic benefit from specific treatments have not yet been performed.

MONITORING RESPONSE TO TREATMENT

Beyond the application of liquid biopsies for early cancer detection and noninvasive tumor genotyping, their use for monitoring therapeutic responses in a quantitative and qualitative fashion deserves discussion. In many cancer types, functional imaging has utility for monitoring systemic response to treatment, when considering relative changes in volumetric and/or metabolic tumor burden to assess complete versus partial responses or stable disease. Similarly, in hematologic malignancies such as chronic myelogenous leukemia, the magnitude of response to systemic therapy with TKIs can be monitored at defined milestones while on continuous treatment, using defined thresholds for reductions in *BCR-ABL1* transcript levels in the blood. Liquid biopsies can be similarly useful for measuring quantitative changes in ctDNA while on therapy. Importantly, as with the use of functional imaging, it is critical to consider several key factors when using quantitative changes in ctDNA levels to monitor response. These include the specific tumor histology and treatment setting (frontline vs relapsed disease), treatment type, the timing of interim ctDNA response assessment, the type of ctDNA assay being used and associated sensitivity and specificity characteristics, and the thresholds for change in ctDNA levels observed as informing early molecular response. For example, liquid biopsy applications for measuring interim responses have been shown to strongly predict survival outcomes in diffuse large B-cell lymphoma and Hodgkin's lymphoma in the frontline setting. Here, 100-fold reductions (2-log) in ctDNA levels after one cycle of induction chemotherapy have been shown to reliably define an early molecular response threshold, and 2.5-log reductions in ctDNA levels after two cycles can be used to define a major molecular response, which are both strongly associated with event-free and overall survival.

MINIMAL RESIDUAL DISEASE

As in the case of several hematologic malignancies, an emerging body of evidence now demonstrates that liquid biopsies including ctDNA can detect MRD following treatment of diverse solid tumor types as a predictor for relapse risk. Indeed, detection of MRD using ctDNA-based techniques has shown strikingly high positive predictive value for predicting relapse risk in many cancer types, including carcinomas of the lung, colon, rectum, bladder, and breast, among others. For example, when considering adjuvant immunotherapy following resection of localized bladder cancers, a retrospective analysis of a randomized clinical trial strongly suggests that clinical utility for the checkpoint inhibitor atezolizumab is likely limited only to patients

with ctDNA MRD detectable in the blood plasma after surgery using bespoke assays. Separately, the Centers for Medicare and Medicaid Services recently finalized the first local coverage determination to provide coverage for ctDNA MRD testing for monitoring colorectal cancers after surgery using the Signatera MRD test from Natera, and a broader draft local coverage determination is currently under consideration to enable coverage of ctDNA MRD across tumor types.

Based on these and other similar results, pivotal clinical trials are now underway that select patients for adjuvant therapy integrating liquid biopsies to detect MRD and to measure response to such adjuvant and consolidative treatments. Of note, despite the high positive predictive value of ctDNA MRD for predicting relapse, the clinical sensitivity of several current assays is generally modest, with a substantial fraction of relapses occurring in patients falsely classified as MRD negative after initial maneuvers. As in the case of early detection and noninvasive genotyping described above, for applications of liquid biopsies to MRD, it is critically important to consider the specific therapies administered, the biology of ctDNA release, the timing of MRD measurements, the liquid biopsy assay performance characteristics, and the sources of both technical and biologic background. For instance, the optimal use of liquid biopsies for their negative predictive value (e.g., by withholding unnecessary adjuvant therapy in those without evidence of MRD) is likely to require substantial additional improvements in the analytical and clinical sensitivity of MRD detection for solid tumors. Nevertheless, although the broad clinical utility of ctDNA MRD for treatment personalization has yet to be fully established, liquid biopsies hold substantial promise for guiding adjuvant and consolidative therapies.

TECHNICAL CONSIDERATIONS

Despite generally representing a small fraction of nucleic acids that circulate in the blood plasma, tumor-derived ctDNA molecules can be identified through a range of techniques related to amplification and detection. These methods broadly include assays that target tumor-specific mutations, structural variants, somatic copy number alterations, and epigenetic features and generally involve using polymerase chain reaction (PCR) and high-throughput sequencing. Recently, substantial improvements in the analytical sensitivity of liquid biopsies have been achieved through a combination of refinements in these molecular techniques and the associated computational methods for analyzing the corresponding data.

Currently, liquid biopsy applications for early cancer detection, noninvasive tumor genotyping, response monitoring, and MRD rely mainly either on sequencing-based methods or on amplicon-based techniques that do not require sequencing, such as digital droplet PCR (ddPCR) or allele-specific PCR (AS-PCR). Key factors that distinguish these methods include the cost and turnaround time for the assays (which are generally in favor of amplicon-based methods), as well as the scope of genomic aberrations simultaneously being evaluated and the breadth and depth of the associated molecular profile (which are generally in favor of sequencing-based methods). For MRD applications, the integration of multiple tumor-specific somatic alterations into a single assay can allow multiplexed sequencing-based strategies to achieve analytical sensitivities in the parts-per-million range, especially in the context of bespoke assays leveraging tumor genotypes.

Among various sequencing-based techniques, liquid biopsy applications have variably profiled the whole human genome or targeted subregions of the genome, depending on the specific applications in oncology. More specifically, selective targeting of portions of the human genome can be achieved either through enrichment by hybridization affinity capture or using locus-specific amplicons, whether focused on the whole coding exome or smaller, more focused genomic regions of interest from tens to hundreds of genes.

The biologic and technical sources of background can limit the sensitivity and specificity of liquid biopsies. Apart from the various strategies described to reduce these sources of error, many liquid biopsy studies monitoring therapeutic response and ctDNA MRD have leveraged tumor genotype–informed analyses to improve performance. Unlike noninvasive genotyping methods that rely entirely on blood plasma, this tumor genotype–informed approach includes the profiling of tumor tissue to identify mutations that are then tracked in posttreatment blood plasma. In reducing the number of mutations under consideration, this approach reduces the risk of false positives due to technical and biologic background sources of error. Separately, the tumor genotype–informed approach can be less demanding for blood sample volumes. However, due to the very low circulating levels of tumor-derived DNA at posttreatment milestones, tracking multiple tumor genotype–informed mutations and minimizing unwanted effects of biologic and technical errors are critical for optimally capturing disease risk in diverse cancers using liquid biopsies to detect ctDNA MRD.

CELL-FREE DNA IN TRANSPLANTATION

cfDNA testing offers very powerful tools for clinical monitoring of organ transplant recipients. After transplantation, cfDNA analyses have been used to assess for development of acute allograft rejection, to study microbial diversity and infection, and to quantify host immunity. This section describes current and potential future clinical applications of cfDNA testing in the transplant arena.

NONINVASIVE DETECTION OF ACUTE ALLOGRAFT REJECTION

In the setting of transplantation, cfDNA is derived from both the recipient tissues and the donated organ or cells. A transplant procedure is essentially a "genome transplant," and methods have been developed to detect and quantify levels of donor-derived cfDNA (dd-cfDNA) after transplant, with elevated levels reflecting graft injury due to acute rejection and other forms of graft damage.

In 1998, Lo and colleagues first reported detection of DNA from the organ donor in the plasma of transplant recipients. By performing PCR amplification using Y chromosome–specific primers, they were able to identify dd-cfDNA in the blood of female kidney and liver transplant recipients. This early work provided proof-of-concept of this unique approach but was limited to female recipients of male donor organs (<25% of transplant procedures).

Subsequently, a universal, sex-independent strategy was developed using whole genome shotgun sequencing to measure single nucleotide polymorphism (SNP) differences between individuals to quantify the donor signal. This approach is applicable to any organ donor and recipient combination, regardless of sex, by first genotyping the donor and recipient to identify sequence differences that can then be used to identify donor cfDNA in the recipient's blood after transplantation. Prospective studies of this approach have demonstrated that dd-cfDNA is present at very high levels during the first few days after the transplant procedure, reflecting cell death within the allograft due to ischemia and reperfusion injury. Within 1–2 weeks after transplantation, however, dd-cfDNA levels fall to a low baseline level and remain constant in the absence of acute rejection.

In the setting of acute rejection, dd-cfDNA levels increase significantly in the transplant recipient's circulation and correlate with severity of rejection. Initial studies in heart transplantation showed that, at a threshold value of 0.25%, dd-cfDNA had an area under the receiver operating characteristic curve (AUC) of 0.60 for distinguishing mild, 0.83 for distinguishing moderate-to-severe, and 0.95 for distinguishing severe rejection events, each compared to the absence of rejection. Notably, this assay can be used for surveillance of both acute cellular and antibody-mediated rejection, as both processes result in graft damage **(Fig. 490-5)**. A subsequent multicenter study confirmed the utility of dd-cfDNA monitoring for acute rejection, showing that, at a threshold of 0.25%, dd-cfDNA had a 99% negative predictive value for acute rejection and would have safely eliminated 81% of routine surveillance biopsy procedures.

Notably, increasing dd-cfDNA levels were detected several weeks to months prior to the rejection event, suggesting that dd-cfDNA is a highly sensitive marker of graft injury and can enable earlier rejection diagnosis. Early detection of graft injury may prompt augmentation of immunosuppressive therapy to halt graft damage in its early stages and to prevent a subsequent rejection event.

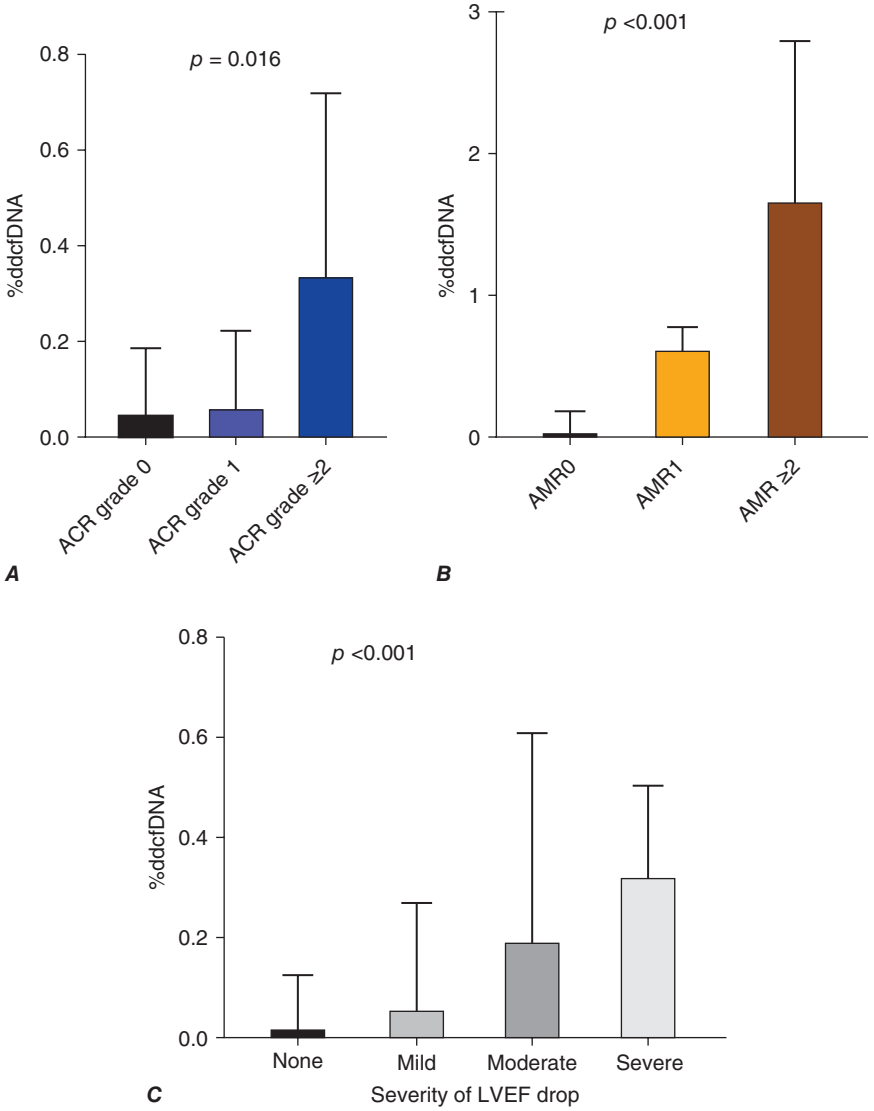

FIGURE 490-5 Correlation of percentage of donor-derived cell-free DNA (%dd-cfDNA) measures with heart transplant biopsy-graded rejection and allograft dysfunction by echocardiography. ***A.*** %dd-cfDNA in relation to severity of acute cellular rejection (ACR) by histopathologic interpretation of endomyocardial biopsy. Grade 0 rejection includes both ACR grade 0 and antibody-mediated rejection (AMR) grade 0. *P* value obtained by generalized estimating equation approach comparing all categories. ***B.*** %dd-cfDNA in relation to severity of AMR by histopathologic interpretation of the endomyocardial biopsy. Grade 0 rejection includes both ACR grades 0 or 1 and AMR grade 0. *P* value obtained by generalized estimating equation approach comparing all categories. ***C.*** %dd-cfDNA in relation to severity of allograft dysfunction measured by echocardiography. Allograft dysfunction was defined as a reduction of left ventricular ejection fraction (LVEF) by ≥5% and was further stratified by severity based on the magnitude of LVEF decline as no (<5%), mild (5% to <10%), moderate (≥10% to <15%), or severe (≥15%) allograft dysfunction. *P* value obtained by generalized estimating equation approach comparing all categories. *(Reproduced with permission from S Agbor-Enoh et al: Cell-free DNA to detect heart allograft acute rejection. Circulation 143:1184, 2021.)*

Finally, the investigators demonstrated higher dd-cfDNA levels associated with antibody-mediated rejection compared to cellular (T-cell–mediated) rejection, as well as different cfDNA fragment types and lengths during these two rejection processes, suggesting that dd-cfDNA patterns could potentially help differentiate these two rejection subtypes.

Parallel studies in lung, kidney, and liver transplantation have also confirmed the utility of dd-cfDNA as a noninvasive acute rejection biomarker.

A large, multicenter, prospective study in kidney transplantation (Diagnosing Acute Rejection in Kidney Transplant Recipients [DART]) enrolled 384 patients, on whom 107 biopsies of the transplanted kidney were performed. The dd-cfDNA level discriminated between biopsies showing any acute rejection and controls (no histologic rejection), with an AUC of 0.74, sensitivity of 59%, and specificity of 85% for acute rejection at a dd-cfDNA cutoff of ≥1.0%. Since publication of the DART study, other investigations of dd-cfDNA in kidney transplantation have shown similar results, with notably high dd-cfDNA levels (median 1.4–2.9%) in patients with antibody-mediated rejection and poorer diagnostic accuracy for patients with early (Banff 1A or borderline) T-cell–mediated rejection. Studies have also shown elevated dd-cfDNA levels in patients who develop donor-specific antibodies, even in the absence of antibody-mediated rejection. In kidney transplantation, dd-cfDNA could be elevated due to pathologies other than rejection (e.g., BK virus nephropathy and pyelonephritis) and is more likely a marker of severe graft injury rather than rejection alone. Thus, follow-up testing to determine the cause and nature of graft injury or use of dd-cfDNA surveillance primarily in patients at high risk of allograft rejection would be reasonable.

Studies in liver transplantation have consistently demonstrated elevated dd-cfDNA levels during episodes of biopsy-proven acute rejection. As in kidney transplantation, levels appear to rise before development of clinical manifestations of acute rejection, with data demonstrating elevated levels 4–6 days before a rise in transaminase enzyme levels and 8–15 days before biopsy confirmation of rejection. It is important to note that steady-state dd-cfDNA levels vary between transplanted organs, likely relative to the organ's mass, cellularity, or vascularization, with levels of 5–10% seen in stable liver transplant recipients and levels <0.1% seen in heart transplant patients.

Similar patterns of dd-cfDNA have also been seen after lung transplantation, with elevated levels detected weeks prior to and at the time of transbronchial biopsy demonstrating acute rejection. As in heart and kidney transplantation, dd-cfDNA levels correlate with severity of the rejection event, with greater discriminatory power seen for severe rejection and higher levels seen in antibody-mediated rejection compared to cellular (T-cell–mediated) rejection.

Donor-derived cfDNA levels also appear to have prognostic value, even in the absence of acute allograft injury. In a lung transplant cohort, patients with the highest average dd-cfDNA levels within the first 3 months after transplant, in the absence of rejection, were at high risk for subsequent chronic allograft dysfunction and allograft failure. Similarly, in kidney transplantation, donor-derived cfDNA levels at hospital discharge were shown to predict graft dysfunction at 1 year after transplant. As such, average dd-cfDNA levels over time may reflect cumulative graft injury and related long-term adverse outcomes.

Over the past few years, targeted next-generation sequencing assays (AlloSure [CareDx, Inc.] and Prospera [Natera]) have been developed to quantify dd-cfDNA levels after transplantation. These assays are composed of panels of highly polymorphic SNPs that, when sequenced and quantified, enable differentiation of donor and recipient cfDNA molecules using bioinformatics approaches. Such assays do not require donor or recipient genotyping, are rapid and relatively cost effective (particularly when compared to whole genome sequencing), and are currently available for clinical use.

In summary, dd-cfDNA can be reliably detected in the plasma of transplant recipients. Levels of dd-cfDNA are high immediately after transplantation but rapidly fall to a baseline level within 2 weeks, after ischemia-reperfusion injury has subsided. These dd-cfDNA levels then remain at stable low levels in the absence of graft injury, with baseline levels varying by organ type, likely related to the mass of the

transplanted organ. Most studies performed to date have demonstrated rising levels with development of acute rejection and other forms of allograft injury, with highest discriminatory power for antibody-mediated rejection and severe grades of acute cellular rejection, and have shown that levels rapidly fall after successful rejection treatment.

dd-cfDNA testing cannot completely replace biopsies of the transplanted organ, which provide valuable immunohistochemical and molecular diagnostic information that helps guide clinical treatment. Rather, this noninvasive assay reduces the need for surveillance biopsies and enables clinicians to selectively perform biopsies on patients for whom they are truly indicated, with attendant improvements in safety, cost, and patient satisfaction. The ultimate goal is to use dd-cfDNA to "personalize" immunosuppressive management by enabling weaning of therapy in stable patients with low dd-cfDNA levels and augmentation of treatment in patients with rising levels suggestive of early graft injury.

MONITORING MICROBIAL DIVERSITY AND INFECTION AFTER TRANSPLANTATION

Immunosuppressive therapies reduce the risk of allograft rejection but increase the transplant recipient's susceptibility to infectious complications. The balance between level of immune system suppression and the competing risks of rejection and infection is delicate, and the desirable "therapeutic window" for patient treatment is narrow. Furthermore, diagnosis of infectious complications after transplantation is challenging, as patients are susceptible to a wide array of pathogens and common diagnostic tests rely on an a priori hypothesis for the source of infection and performance of specific antigen-based or PCR-based molecular tests. Hypothesis-free sequencing of the microbial component of transplant recipients' cfDNA offers a window into the state of the immune response and potential diagnosis of infectious complications.

In 2013, De Vlaminck et al performed shotgun sequencing of heart and lung transplant recipient cfDNA followed by alignment to reference human and microbial databases. This work showed that 2% of cfDNA sequences were microbial in origin, including viral, bacterial, and fungal genomes. They then studied the microbiome composition in plasma at different levels of taxonomic classification and showed that viruses (73%) are more abundant than bacteria (25%) and fungi (2%). Subsequent testing showed quantitative agreement between viral counts as measured by sequencing and quantitative PCR assays for common posttransplant viral pathogens such as herpesviruses.

Available data on clinical drug treatment and dosage, including calcineurin inhibitor use and antiviral prophylaxis, were used to analyze drug-microbiome interactions. The investigators found that the structure of the virome is exquisitely sensitive to drug use and dosage—high doses or levels of immunosuppressive drugs give rise to a virome dominated by *Anelloviridae* or torque teno viruses, which are ubiquitous viruses that have no known pathogenic role in humans but have been shown to replicate in the setting of immune system suppression. Similarly, the relative amount of herpesviruses declines substantially after introduction of the prophylactic antiviral agent valganciclovir **(Fig. 490-6)**. Using this approach, the investigators demonstrated dramatic changes in the viral composition of the microbiome in response to introduction and weaning of immunosuppressive and antiviral therapies after transplantation.

Using a similar approach, De Vlaminck and colleagues analyzed nonhuman cfDNA as a hypothesis-free approach to test for infectious complications after lung transplantation. They showed that levels of cytomegalovirus-derived sequences in cfDNA correlated well with clinical testing results (AUC 0.91). They also identified adenovirus, polyomavirus, herpesvirus, and microsporidia sequences in patients with clinical infections that had eluded diagnosis, suggesting that

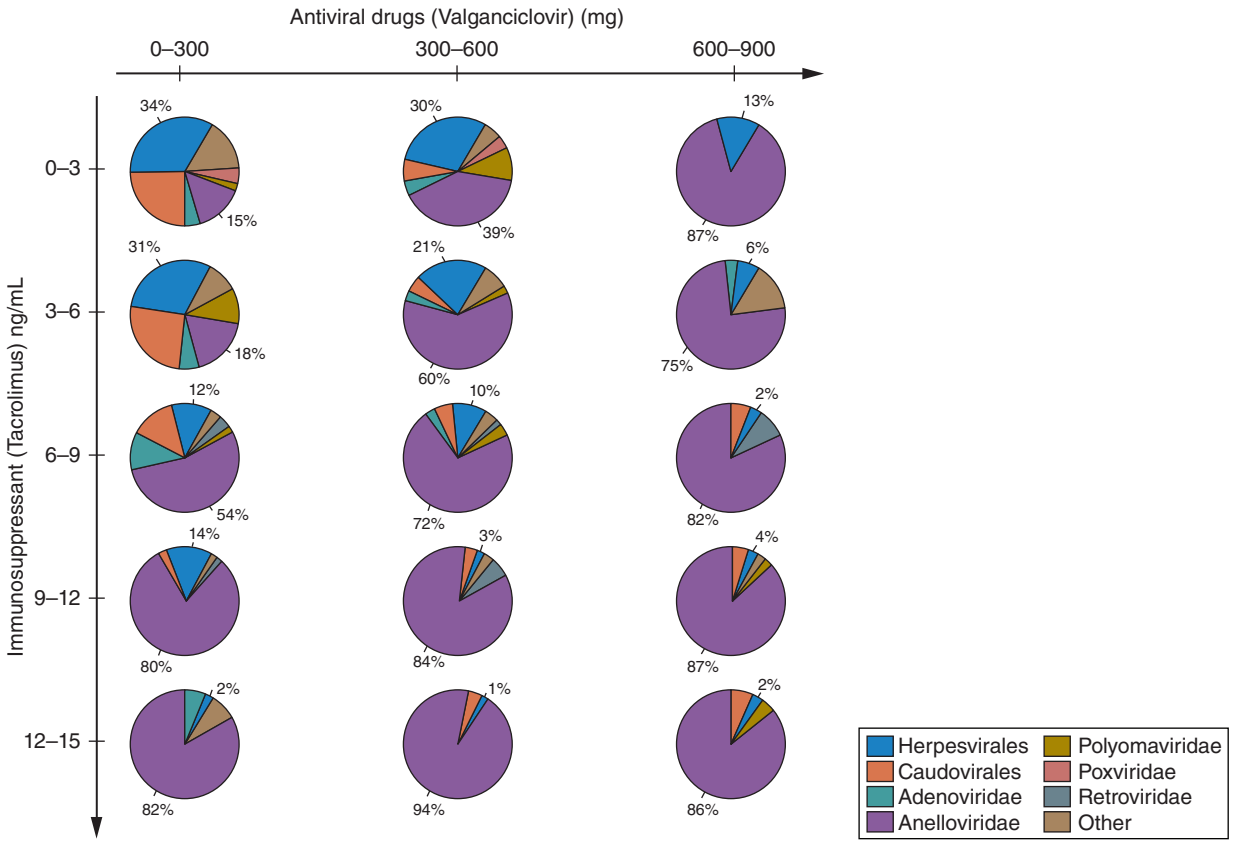

FIGURE 490-6 Relative viral genomic abundance as a function of drug dose in a cohort of heart and lung transplant recipients. Mean virome composition for patients treated with the immunosuppressant tacrolimus (47 patients, 380 samples) as a function of antiviral drug dose (valganciclovir) and concentration of tacrolimus measured in blood. To account for the delayed effect of the virome composition on drug dose, the data on drug doses were window average filtered (window size, 45 days). Herpesvirales and caudovirales dominate the virome when patients receive low doses of immunosuppressants and antiviral drugs. Conversely, anelloviridae dominate the virome when patients receive high doses of these drugs. *(Reproduced with permission from I De Vlaminck et al: Temporal response of the human virome to immunosuppression and antiviral therapy. Cell 155:1178, 2013.)*

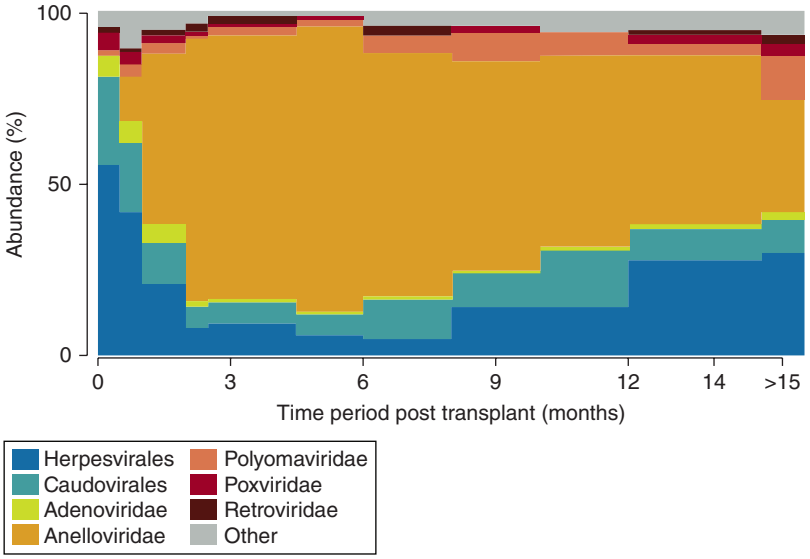

FIGURE 490-7 Viral genome abundance at the family and order level of taxonomic classification for different time periods after heart and lung transplantation. The fraction of anelloviridae expands rapidly in the first several months after transplantation. The fractions of herpesvirales, caudovirales, and adenoviridae decrease in that same time period. After 6 months, the opposite trends are observed. *(Reproduced with permission from I De Vlaminck et al: Temporal response of the human virome to immunosuppression and antiviral therapy. Cell 155:1178, 2013.)*

cfDNA sequencing can be a powerful approach for nonbiased diagnosis of opportunistic infections after transplantation. However, several obstacles to clinical implementation must first be overcome, including the establishment of pathogen-specific thresholds to discriminate between colonization, infection, and disease.

MONITORING HOST IMMUNITY

As mentioned previously, De Vlamink and colleagues demonstrated that the *Anelloviridae* family of viruses predominated in the virome of lung transplant recipients, as analyzed by plasma cfDNA sequencing, and accounted for 68% of the total viral population. The relative abundance of anellovirus cfDNA is exquisitely sensitive to immunosuppression, ranging from <5% prior to transplant (e.g., in the nonimmunosuppressed state) to 84% during months 4.5–6 after transplantation, when immunosuppression is most profound. Starting at 6 months after transplantation, the relative amount of anellovirus cfDNA declines, corresponding to a reduction in intensity of immunosuppression (Fig. 490-7).

The observation that anellovirus cfDNA levels rise and fall with degree of immune system suppression gave rise to the hypothesis that the abundance of this ubiquitous family of viruses could be used as a marker of the overall strength of the immune response. Indeed, a global marker of the net state of immunosuppression has eluded transplant physicians to date, who currently quantify doses and levels of individual immunosuppressive drugs but cannot reliably assess for their effect or potency in combination. In support of this hypothesis was the subsequent observation that anellovirus load was lower (reflecting less immunosuppression) in lung transplant recipients who developed acute rejection and was relatively high (indicating more profound immunosuppression) in patients who had a rejection-free posttransplant course, suggesting that the anellovirus cfDNA load could be a surrogate marker of immunocompetence.

Subsequent studies have confirmed these observations after different solid organ transplant procedures (Fig. 490-8). A prospective lung transplant study showed a hazard ratio (HR) of 5.05 for infectious complications and an HR of 0.48 for acute rejection with every $\log_{10}$ increase in anellovirus load. Similar results have been shown after liver and kidney transplantation, with higher anellovirus levels associated with opportunistic infections and malignancy (sequelae of chronic immunosuppression) and lower levels associated with acute rejection and chronic allograft dysfunction. While much work remains to be done in this arena, including standardization of anellovirus assays and quantification, prospective studies with well-defined sampling schedules and endpoints, and improved understanding of genotype-specific effects on host immunity, the potential to use anellovirus cfDNA load as a marker to titrate and personalize immunosuppressive therapy may be within reach.

In summary, cfDNA sequencing has myriad clinical applications after solid organ transplantation. Donor-derived cfDNA assays are currently available for acute rejection monitoring and are being used for noninvasive surveillance after heart, lung, and kidney transplantation. These assays are highly sensitive, provide early detection of allograft injury, and can also be used to monitor response to rejection therapy. cfDNA sequencing can also be used to monitor changes in the microbiome after transplantation, in response to alterations in immunosuppression and antimicrobial therapy, and can potentially be used to diagnose opportunistic infections. Finally, quantification of anellovirus cfDNA load offers the possibility of assessing the overall status of the host immune response, which is a necessary first step for providing individualized immunosuppressive therapy to transplant recipients.

CELL-FREE DNA IN PRENATAL MEDICINE

Fetal genetic disorders are among the leading causes of stillbirth, neonatal death, and long-term developmental delay. Prenatal diagnosis of fetal genetic conditions relies on invasive sampling of fetal tissues via either amniocentesis (sampling of amniotic fluid) or chorionic villus sampling (CVS; sampling of placental tissue). Prenatal diagnostic

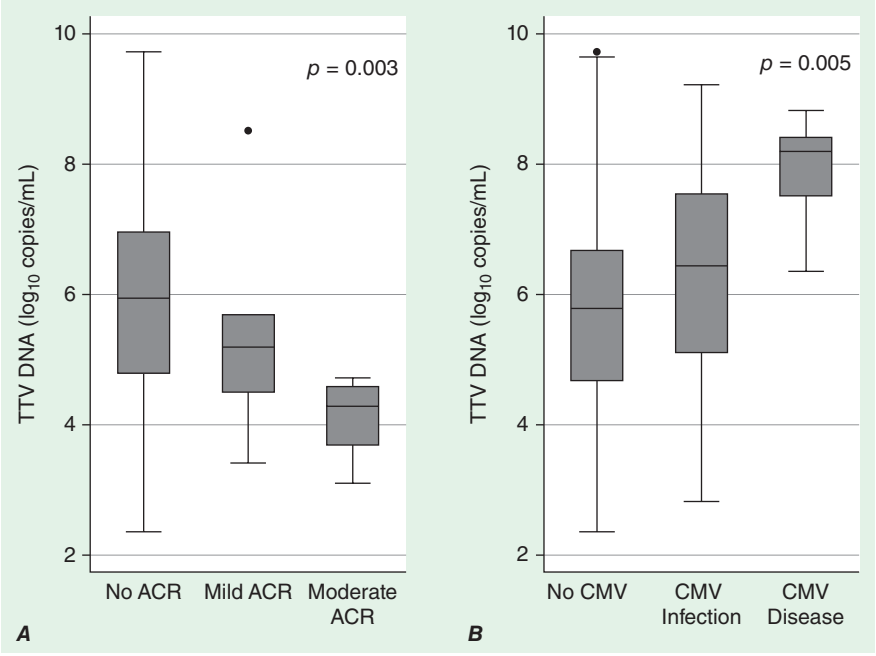

FIGURE 490-8 TTV (torque teno virus, anellovirus) load during (*A*) episodes of acute cellular rejection (ACR) and (*B*) cytomegalovirus (CMV) infection and disease after liver transplantation. *(Reproduced with permission from P Ruiz et al: Torque teno virus is associated with the state of immune suppression early after liver transplantation. Liver Transpl 25:302, 2019.)*

tests are invasive, ultrasound-guided, needle-based procedures that unfortunately carry a small risk of miscarriage, preterm rupture of the membranes, and preterm birth. Historically, safer noninvasive screening for fetal genetic disorders, particularly aneuploidy (chromosomal copy number abnormalities such as trisomy 21 or Down's syndrome), was performed by combining maternal serum analyte levels (e.g., pregnancy-associated plasma protein A [PAPP-A], β-human chorionic gonadotropin [β-hCG], α-fetoprotein [AFP], inhibin) with sonographic assessment of the fetal nuchal translucency (a measurement of the distance between the scalp and skin in the area of the fetal neck). While traditional prenatal screening is safer than invasive diagnostic tests, these modalities suffer from lower detection rates and higher false-positive rates. Recent advances in cell-free fetal DNA technology have introduced safe noninvasive prenatal tests with much higher accuracy than traditional screening. This section describes the use of cell-free fetal DNA testing in prenatal medicine.

NONINVASIVE PRENATAL TESTING FOR FETAL ANEUPLOIDY

Passage of fetal cells into the maternal bloodstream was initially described almost 80 years ago. A mismatch between fetal red blood cells and maternal red blood cells was subsequently identified as the cause of isoimmunization and hydrops fetalis, a potentially lethal condition in which maternal antibodies develop against "foreign" fetal red blood cell antigens. With the development of Rho(D) immune globulin (RhoGAM) and its use to prevent RhD isoimmunization in RhD-negative mothers carrying RhD-positive pregnancies, attention then turned toward targeting fetal red blood cells for the detection of fetal aneuploidy. This is because fetal red blood cells contain a nucleus and genomic material, whereas maternal red blood cells do not. Unfortunately, initial research endeavors in the area failed to yield significant results due to several inherent limitations. First, the number of fetal red blood cells circulating among the more prevalent maternal red blood cell background is quite small. Second, the half-life of the circulating fetal red blood cells in maternal serum was found to be quite long, and circulating cells may actually originate not just from the current pregnancy but even from a prior pregnancy. Finally, the technology available at the time, namely fluorescent-activated cell sorting, was unable to accurately separate the cells to isolate the fetal cells from the maternal background.

In 1990, Lo and colleagues determined that cell-free fetal DNA, and not just fetal cells, crosses the placenta and could serve as a target for fetal aneuploidy detection. This was subsequently confirmed when the presence of DNA from the Y chromosome was found in the serum of pregnant women carrying a male fetus. Over the next two decades, cfDNA circulating in maternal blood was characterized, and different genetic techniques were employed to delineate differences between cell-free fetal DNA and cell-free maternal DNA. Cell-free fetal DNA has several advantages as a diagnostic target over circulating fetal cells. First, the fraction of fetal DNA is much higher (~5–20%) than the fraction of fetal cells in maternal circulation. Second, cell-free fetal DNA declines within days of delivery, thereby reducing the risk of DNA from previous pregnancies leading to erroneous results.

Unfortunately, in the case of fetal aneuploidy detection, the actual sequence of fetal DNA from the chromosome of interest is identical to the maternal DNA sequence, and the challenge is to distinguish one from the other. In the early 2000s, the most promising technique for distinguishing fetal from maternal DNA was leveraging epigenetic differences between the two, particularly in the chromosomes of interest, namely chromosome 21 and chromosome 18. In 2008, two landmark studies, one by Chiu and colleagues and one by Fan and colleagues, described the utility of massive parallel sequencing technology as a counting method for noninvasive detection of fetal aneuploidy. This sequencing technology allowed for a comparison of the number of sequencing reads from chromosome 21 against an expected reference number of reads. In other words, if more sequences from chromosome 21 were found in maternal serum than what one would expect, the fetus was suspected of having Down's syndrome. While these findings were based on analysis of limited cohorts, subsequent trials in more robust and diverse cohorts confirmed these findings, and cfDNA testing became an approved clinical test in 2011.

While the initial focus of cfDNA testing was on pregnant women at high risk for fetal aneuploidy (e.g., advanced maternal age, high-risk status based on serum analyte screening, presence of fetal structural anomalies), subsequent studies confirmed the utility of cfDNA technology in both high-risk and low-risk cohorts, opening the path for widespread adoption. Today, the detection rate for the common aneuploidies (trisomies 21, 18, and 13) and for sex chromosome aneuploidy using cfDNA testing is >98% (trisomy 21 detection as high as 99.8%), and cfDNA testing is offered by both private companies and several public nationwide screening programs. The positive predictive value of these tests is variable and dependent on a priori maternal risk; therefore, most societal guidelines recommend confirmatory/diagnostic testing using amniocentesis or CVS in cases of positive cfDNA testing.

NONINVASIVE PRENATAL SCREENING VERSUS NONINVASIVE PRENATAL DIAGNOSIS VERSUS NONINVASIVE PRENATAL TESTING

When data from clinical trials proved the improved performance of cfDNA testing over traditional screening, it became unclear whether to classify the test as *noninvasive prenatal screening* (NIPS) or n*oninvasive prenatal diagnosis* (NIPD). On the one hand, cfDNA testing leverages circulating segments of fetal DNA in maternal serum, unlike traditional screening, which is dependent on indirect analytes such as PAPP-A or β-hCG. On the other hand, variable positive predictive values for different aneuploidies still did not reach the diagnostic accuracy of amniocentesis or CVS, and most cfDNA segments originate from the placenta, rather than from the fetus. Therefore, over time, the label of *noninvasive prenatal testing* (NIPT) became commonly used in both the scientific literature and the lay literature. Today, much confusion remains for both patients and providers as to the accuracy of these tests and their inherent limitations.

DEPENDENCE ON FETAL FRACTION

As clinical experience with NIPT grew, it became clear that the accuracy of the test depends on the fraction of fetal DNA in maternal serum. While fetal DNA can be found in maternal serum as early as 4–5 weeks' gestation, the fetal fraction increases with gestational age, and most NIPT programs recommend testing after 10 weeks' gestation. Although each NIPT company or national NIPT program uses a different fetal fraction cutoff to accurately report a result, a small percentage of patients will receive a "no call" or uninterpretable result due to low fetal fraction. Factors leading to "no call" also include early gestational age (usually <10 weeks), maternal obesity, underlying maternal autoimmune disease or malignancy, and vanishing twin (twins in which one fetus demises early in gestation). Several studies suggested an association between a no-call result and increased risk for aneuploidy, and the appropriate management of a no-call result remains controversial, with some recommending a repeat NIPT test, while others recommend invasive diagnostic testing given the increased aneuploidy risk.

NIPT IN MULTIPLE GESTATIONS

While initial results questioned the utility of NIPT in multiple gestations, more recent reports from large cohorts suggest that the aneuploidy detection rate in twins mirrors that in singletons. Moreover, many NIPT programs report zygosity in cases of multiple gestations. This is particularly important since one would assume that NIPT results from monozygotic twins (twins originating from a single embryo) would indicate the presence of euploidy or aneuploidy in both twins, and zygosity testing is also important when the number of placentas has not been determined or remains unclear based on sonography. Monochorionic twins (all of whom are monozygotic twins) are considered higher risk than dichorionic twins (most of whom are dizygotic twins but can also be monozygotic twins) and are managed differently. Newer NIPT platforms can also distinguish the presence of aneuploidy in a single fetus in cases of dizygotic twins. NIPT is still not validated for triplet gestations or multiple gestations in which a single fetal reduction or fetal loss occurs.

NIPT FOR FETAL MICRODELETION/ DUPLICATION SYNDROMES

Advanced molecular technologies, particularly chromosomal microarray (CMA), are now the preferred diagnostic method when performing amniocentesis or CVS, particularly in the setting of a known fetal anomaly or fetal growth restriction. Unlike traditional karyotype, which relies on the visual assessment of chromosomes by a cytopathologist with a resolution of ~5–10 MB, CMA is an automated molecular technique that can identify differences as small as a single nucleotide. The main benefit of CMA over traditional karyotype is in its ability to detect copy number variants such as microdeletion/duplication syndromes (e.g., 22q11 microdeletion or DiGeorge's syndrome). Although the focus of NIPT was initially on the prenatal detection of Down's syndrome and other aneuploidies, the potential for NIPT to detect smaller chromosomal rearrangements, including copy number variations (CNVs), was recently evaluated and introduced into clinical care. This is important because CNVs carry a significant neonatal disease burden, and the risk of such variants may be more common than Down's syndrome among young pregnant women. Unfortunately, the detection rates for such conditions by NIPT are not as robust as they are for aneuploidy detection, and the positive predictive values are lower. Moreover, because most cell-free fetal DNA originates from the placenta, there is concern that confined placental mosaicism may result in erroneous NIPT results that target smaller genomic aberrations. High false-positive rates may lead to unnecessary parental anxiety, increased rates of invasive confirmatory testing, and pregnancy termination.

WHOLE GENOME NIPT AND SINGLE-GENE DISORDERS

Most NIPT platforms use next-generation sequencing to obtain DNA reads covering the entire genome but only report a fraction of the sequences analyzed. This has led to a debate as to whether whole genome NIPT should be offered and reported. As with any robust and comprehensive test, questions regarding false-positive rates and abnormalities of unclear significance are being considered. Also, whether to limit the results to known disease-causing mutations remains controversial. While whole genome NIPT is being considered, NIPT platforms targeting single-gene disorders have been recently developed, and these are slowly becoming clinically available. This is a significant advance because maternal carrier screening of single-gene disorders is becoming more prevalent, with clinically available comprehensive gene panels covering hundreds of potential disease loci. In the absence of NIPT, couples deemed at risk based on maternal and/or paternal carrier screens (e.g., an asymptomatic couple in which both parents are heterozygous for an autosomal recessive gene mutation such as cystic fibrosis) would need to undergo an invasive diagnostic procedure in order to confirm or exclude a significant fetal condition (homozygous for an abnormal cystic fibrosis gene).

NIPT USING CELL-FREE RNA

Cell-free fetal DNA is not the only nucleic acid found in maternal serum. Cell-free fetal RNA is also present, providing a unique snapshot of which genes are being transcribed at any given time in pregnancy. Cell-free fetal RNA can also be linked to tissue-specific genes, offering a unique window into developing fetal organs. Moreover, serial analysis of the pregnancy transcriptome and comprehensive analysis of cfRNA in maternal serum over time have been studied as means of early detection of common third-trimester obstetric complications including preeclampsia, fetal growth restriction, and preterm birth.

NIPT DETECTING MATERNAL MALIGNANCY

Maternal malignancy complicates approximately 1 in 1000 to 1 in 1500 pregnancies. Common cancers include hematologic, breast, and gynecologic cancers, including cancers of the cervix and ovary. Because next-generation technologies sequence both maternal and fetal DNA, changes in DNA levels may not only indicate fetal disorders but also maternal disease. While most uninterpretable NIPT tests result from low fetal fraction or other fetal and/or placental conditions, a small subset may be due to undiagnosed maternal malignancy. Cases of maternal lymphoma, leukemia, gastrointestinal malignancy, and neuroendocrine tumors detected incidentally by NIPT have been described in the literature.

BEYOND NEXT-GENERATION SEQUENCING

While most NIPT platforms use next-generation sequencing technology, some studies have analyzed the utility of digital PCR and fetal cell analysis for NIPT. Digital PCR has been described as a useful tool for testing pregnancies at risk of X-linked and autosomal recessive single-gene disorders for both single mutations and compound heterozygous mutations. Although original attempts to isolate circulating fetal cells were abandoned >20 years ago, recent advances have led to new technologies targeting both circulating fetal nucleated red blood cells and trophoblasts. This progress, still in the research phase, suggests that it may be possible to identify and isolate single cells as early as the first trimester and analyze them by whole-gene genome amplification followed by copy number analysis using arrays or next-generation sequencing.

SUMMARY

Collectively, the uses described in this chapter summarize some of the myriad clinical applications of liquid biopsy methods including cfDNA profiling in oncology, transplantation medicine, and obstetrics. For each area, several existing assays have enabled transformative approaches to noninvasive diagnosis of disease, assessment of associated risk, and assessment of therapeutic responses. For example, several tumor-derived cfDNA assays are currently available for early cancer detection, noninvasive genotyping, response assessment, and MRD monitoring across diverse cancer types. Liquid biopsy assays for oncology can provide highly sensitive measures of tumor burden and associated risk and can also be used to monitor response to anticancer therapies. Prominent among applications of liquid biopsies is the detection of MRD following definitive therapy for solid cancers as a strongly prognostic biomarker with very high positive predictive value for risk of recurrence. Similarly, cell-free nucleic acids have transformed transplantation medicine. Rising levels of donor-derived cfDNA can indicate acute allograft rejection, and clinical dd-cfDNA assays are now being used for noninvasive rejection surveillance in lieu of invasive biopsy procedures. Microbial cfDNA analysis can potentially be used to screen for opportunistic infections after transplantation and for the hypothesis-free diagnosis of posttransplant infections, and such clinical assays are currently in development. Moreover, quantification of particular microbial cfDNA sequences, such as that of the *Anelloviridae* family, could one day enable transplant physicians to assess the overall status of the alloimmune response—a goal that could enable personalization of immunosuppressive therapy to maximize efficacy and to prevent the long-term toxicities associated with these medications. Finally, detection of cell-free fetal or placental DNA has improved the prenatal detection of fetal aneuploidy and other genomic abnormalities. Accordingly, the potential of these liquid biopsy techniques is rapidly expanding and places us at the cusp of a revolution in personalized management of patients across medical disciplines using innovative noninvasive techniques.

491 Protein Folding Disorders

Richard I. Morimoto, G. Scott Budinger

Many hundreds of human diseases, collectively known as protein conformational diseases or protein folding disorders, result from protein misfolding due to intrinsic and extrinsic errors amplified by exposures to environmental and physiologic stress conditions. Despite many years of considerable effort, there remains no useful algorithm that can effectively predict protein tertiary (three-dimensional) structure from primary amino acid sequence (and its variants), let alone posttranslationally modified (from environmental exposures) primary sequence. Such events challenge the integrity of the proteome and can lead to premature clearance, mislocalization, dysfunction or aggregation of proteins, thus affecting cellular robustness, health, and longevity. Mismanagement of the proteome is the basis of a broad class of hundreds of diseases that include orphan lysosomal storage diseases, type 2 diabetes, cystic fibrosis, certain fibrotic diseases, metabolic diseases, muscle wasting diseases, cancer, and neurodegenerative diseases, as exemplified by Alzheimer's disease, frontotemporal dementia, Parkinson's disease, amyotrophic lateral sclerosis (ALS), and Huntington's disease **(Fig. 491-1)**. For each of these diseases and many others described in this textbook, aging is the major contributing risk factor.

The challenge at the biochemical and molecular level is for the cell to achieve a stable and functional proteome during development that persists through young adulthood and to maintain it throughout aging. For humans, this is necessary for the operational health of each of the tens of trillions of cells that compose our ~80 organs for health span and life span. To achieve this goal, our cells have evolved a remarkably efficient proteostasis network (PN) composed of molecular chaperones and other highly conserved components essential for normal protein synthesis, folding, translocation, and degradation **(Fig. 491-2)** that balances input with output and that ensures every protein is functional. The PN is essential for all tissues and for the diverse protein-protein interactions required for cell signaling, biosynthetic processes, and the structural demands for tissue shape, mechanical properties, and function. An equal, if not more important, role for the PN is to detect, prevent, and remove misfolded and aggregated proteins that accumulate in stress, aging, and disease and that thereby interfere with cellular health. Understanding how proteostasis is achieved and maintained is of fundamental biological interest and essential to prevent age-associated protein folding disorders.

All organisms use an evolutionarily conserved set of molecular machines for the synthesis, folding, transport, and removal of unnecessary and damaged proteins. The PN evolutionarily has adapted to the highly specific physiologic requirements of tissues and the expression of abundant and rare proteins with wide-ranging solubilities, folding requirements, stabilities, and structural demands. Added to this complexity of natural clients for the PN is the additional load generated by genetic mutations carried in natural populations and environmental stressors that challenge the capacity of the PN. Despite the central role of proteins as the workhorse of the cell, they are highly susceptible to molecular damage, whether due to intrinsic metastability or genetically inherited mutation or because of error-prone synthesis. Hence, dysfunction in the PN may clinically manifest as either a gradual decline in homeostatic function as occurs with genetic mutations or a loss of resilience in the face of environmental stressors. Thus, clinicians see the consequences of proteostasis failure and cellular dysfunction in both the myriad disorders that present to them as age-associated clinical problems and the increased morbidity and mortality associated with trauma, infection, and other acute illness requiring hospitalization in older individuals.

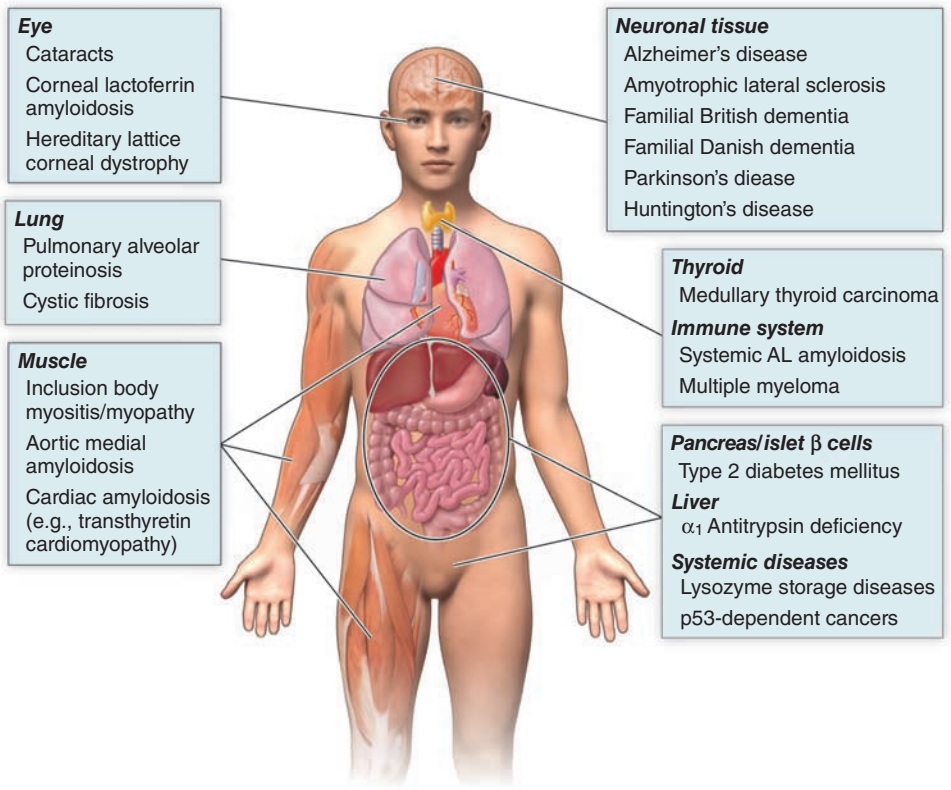

FIGURE 491-1 Diseases of protein folding. A representative list of tissues and known folding diseases.

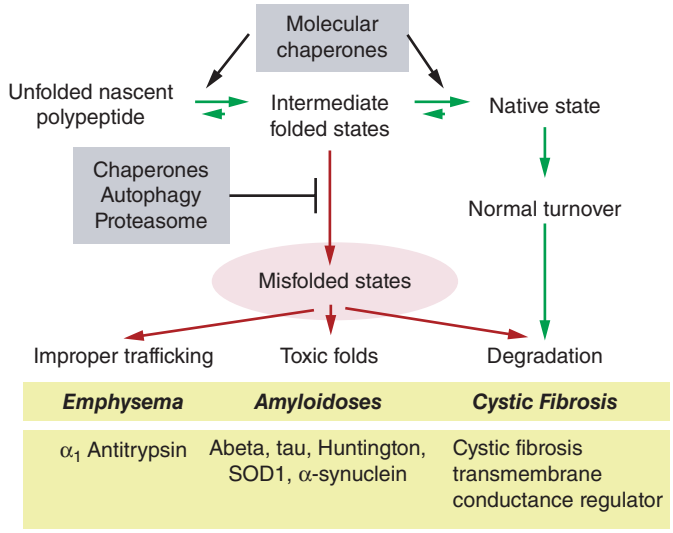
PROTEIN QUALITY CONTROL MECHANISMS

The PN monitors and controls the flux of protein synthesis in order to promote functional folding and to minimize the accumulation of off-pathway aggregation-prone intermediates by their selective disaggregation or degradation. However, unlike an automobile assembly plant for which each item is designed and engineered for assembly into functional components, the properties of the PN tolerate the tremendous chemical noise and diversity generated by coding region polymorphisms and biosynthetic errors among its client components, while maintaining the ability to recognize and remove kinetically unstable conformational states of proteins that would compromise assembly and function. Proteins are highly sensitive to fluctuations in their intracellular environment caused by shifts in energetics, pH, oxidizing and reducing conditions, and the myriad of small



Emphysema	*Amyloidoses*	*Cystic Fibrosis*
α_1 Antitrypsin	Abeta, tau, Huntington, SOD1, α-synuclein	Cystic fibrosis transmembrane conductance regulator

FIGURE 491-2 The proteostasis network and protein folding diseases. The process of protein biogenesis involves the action of molecular chaperones to ensure the transition of the unfolded nascent polypeptide through intermediates to the folded native state. Such proteins then have a natural turnover. Off-pathway species are prevented by the actions of chaperones and the recognition of nonnative misfolded states and aggregates by the autophagic-lysosomal machinery and the ubiquitin-proteasome. When misfolded species escape quality control, they can then become improperly trafficked, as occurs for α_1 antitrypsin associated with emphysema; for toxic folds as occurs for amyloid beta, tau, huntington, and SOD1 in amyloidogenic neurodegenerative diseases; or prematurely degraded as occurs for cystic fibrosis transmembrane conductance regulator (CFTR) associated with cystic fibrosis.

molecules and metabolites that affect folding and function. Added to this range of perturbations are the effects of external stress caused by elevated temperatures, infections, abnormal redox environments, or osmolytes that can have profound consequences on protein-folding thermodynamics, kinetics, and function. These intracellular and extracellular stress conditions, if not properly addressed, would be predicted to amplify further protein instability from sequence polymorphisms and biosynthetic errors that contribute to the stress of protein misfolding. The PN is organized at the cellular level into a series of highly coordinated molecular machines that direct the expression, biogenesis, and functional health of essentially all proteins (Fig. 491-2). Serving more than as regulator and orchestrator of these highly synchronized events, the PN is essential for protein quality control and prevention of the appearance of off-pathway conformational states and accumulation of aggregates and amyloid species. Proteome health involves the constant exchange between the intrinsic physicochemical properties of polypeptides and the biological milieu of the cellular environment in which protein sequences and function evolved.

Beginning with the synthesis of the nascent polypeptide on the ribosome, ribosome quality control (RQC) factors and cytoplasmic chaperones of the HSP70, HSP90, DNAJ/HSP40, chaperonin/HSP60, and small heat shock proteins (sHSPs) family ensure co-translational and posttranslational folding for the cell. Approximately 60% of the proteome resides in the cytoplasm and nucleus, for which the RQC, HSP70, HSP90, and HSP60 chaperones regulate the folded state of client proteins, together with co-chaperones, through cycles of ATP binding and hydrolysis. Chaperones of the HSP70 and J-domain family are particularly well studied for their ability to interact transiently with nascent polypeptides in protein synthesis through short, dispersed, hydrophobic regions using the energy from nucleotide hydrolysis to stimulate the release of partially folded intermediates that either reenter the chaperone cycle or are in a folded native state. For other clients, such as transcription factors, kinases, phosphatases, and signaling molecules, folding to the functional state is regulated and dependent upon interactions with the HSP90 chaperone and other regulatory co-chaperones to form stable heteromeric complexes to maintain the client in a partially folded state primed for subsequent regulated release.

Consistent with the recognition that the formation of off-pathway aggregates is a kinetic component of proteostasis are the concerted activities of disaggregase machines that can unravel protein aggregates into the unfolded, extended polypeptide chain. These disaggregases correspond to the AAA^+ proteins, corresponding to ClpB in bacteria and Hsp104 in yeast and plants and functionally related to a redirected HSP70 machine in other eukaryotes and metazoans that interacts with HSP110 and specific combinations of J-domain proteins capable of inducing disaggregation.

The subcellular organelles, the mitochondria, and endoplasmic reticulum (ER) are responsible for ~20% of the proteome. Chaperone interactions are essential to maintain the extended polypeptide chain in a recognition-competent state for the respective organellar receptors required for translocation across membranes. Upon import, each translocated polypeptide is met by organellar-specific chaperones of the HSP70 and J-domain family for folding and assembly. While the mitochondrial genome encodes 13 proteins required for electron transport, the great majority of mitochondrial proteins are encoded by the nuclear genome, synthesized in the cytosol, and then imported across the outer and inner mitochondrial membranes. Hence, maintenance of the mitochondrial proteome relies on both the cytosolic and mitochondrial PN. For translocation into the lumen of the ER, the extended polypeptide interacts with a set of glycosyltransferases, calnexins, calreticulins and disulphide isomerases. Proteins that misfold in the ER are recognized and retrotranslocated to the cytoplasm, where they are directed to the ubiquitin-proteasome system (UPS) for unfolding and degradation.

The PN is balanced by the essential catabolic processes of the ubiquitin-proteasome and the autophagy-lysosomal machines that recognize proteins for degradation and recycling. The UPS is generally considered the primary pathway by which most proteins are recognized and tagged for degradation; the autophagy-lysosome system is highly responsive to nutrient changes and damage, recognizing and engulfing organelles and other subcellular compartments and large aggregates and inclusions. In addition to their role in the regulated turnover of cellular proteins, these degradation systems are essential for protein quality control and for limiting the accumulation of misfolded and aggregated proteins during stress conditions, aging, and disease.

Protein turnover by the UPS involves an enzymatic cascade of E1, E2, and E3 enzymes that utilize ubiquitin to tag clients, followed by degradation of the polyubiquitinated substrates by the 26S proteasome. Client specificity involves the large family of ~600 ubiquitin ligases. In addition to their roles to mark proteins for degradation, the ubiquitination machinery has numerous additional functions in cellular processes. For example, the ubiquitin ligase listerin is associated with the ribosome and ubiquitinates nascent chains that stall in translation to prevent the accumulation of aberrant polypeptides that would subsequently aggregate. Ubiquitination of these nonnative clients by the ubiquitin ligase activity of the co-chaperone CHIP is central to the triage decision of the HSP70/HSP90 complex between client folding and proteasome-mediated degradation. ER-targeted clients that are misfolded are retrotranslocated to the cytoplasm, polyubiquitinated, and degraded by cytosolic proteasomes in a process termed *ER-associated degradation* (ERAD). Ubiquitination also provides cross-talk between the proteasome and autophagy pathways by targeting clients for lysosomal degradation and for endosomal sorting. Chaperones co-label a protein as nonnative, recruiting other proteins that place ubiquitin chains on the damaged protein for degradation by the proteasome. Alternatively, chaperones can label proteins or protein aggregates to target them to the lysosome. In this process, damaged proteins are degraded by the lysosome, an intracellular organelle with an acidic environment enriched in proteases, through autophagy.

While there is a good general understanding of the process of in vivo chaperone-dependent protein folding, the details of how decisions are made for each client in the cell—whether and for how long to be maintained in a nonnative folding state through chaperone interactions in a nucleotide-independent state, or to assemble into a stable chaperone complex for subsequent assembly into a functional state, or to interact with chaperones to fold directly to a native state—remain to be fully addressed.

CELL STRESS RESPONSES: SENSORS AND REGULATORS OF PROTEIN DAMAGE

Cell stress responses are ancient genetic networks that detect, adapt to, and protect all cells against toxic environmental stressors and physiologically relevant changes in their cellular environment **(Fig. 491-3)**. At the core of these cell stress responses are molecular switches: (1) the heat shock response (HSR) that protects proteins in the cytoplasm and nucleus controlled by HSF-1; (2) the unfolded protein response (UPR) of the ER (UPR^{ER}) controlled by XBP1, ATF6, and ATF4; (3) the UPR of the mitochondria (UPR^{mito}) controlled by ATFS1; (4) the DAF-16/FOX-O stress response pathway associated with insulin signaling; and (5) the antioxidant stress response regulated by NRF-2. Collectively, these cell stress responses and their respective transcription factors are each essential for all cells and tissues and are regulated both autonomously and cell nonautonomously across tissues in metazoans to detect proteotoxic stress and to adapt to and protect the cell against the toxic consequences of protein damage. While each of these cell stress pathways can be activated independently, they are also induced in different combinations according to the chemical and physiologic properties of the stress signal(s) and provide cross-protective mechanisms.

The HSR is an evolutionarily conserved cellular defense mechanism that protects cells against proteotoxicity associated with misfolding, aggregation, and proteome mismanagement. HSF-1 inducibly regulates transcription of genes encoding molecular chaperones and components of the PN. In unstressed cells, HSF-1 is cytoplasmic or nuclear and exists in an inert monomeric state negatively regulated by weak interactions with the molecular chaperones HSP70 and HJD-1. Upon heat shock stress, HSF-1 rapidly trimerizes to acquire DNA-binding activity and undergoes extensive posttranslational modifications, binds to heat shock elements in promoters of stress responsive genes, and relocalizes into nuclear stress bodies. Upon dissipation of the stress signal, attenuation of the HSR involves the active repression of HSF-1 DNA binding through acetylation and loss of HSF-1 transcriptional activity by reassociation with HSP70 and other molecular chaperones and with HSBP1, leading to dissociation to the monomeric inert state. In addition to HSF-1 being essential for the HSR and cell and organismal stress resilience, HSF-1 is essential during early development in metazoans, functions as a maternal factor for gametogenesis, regulates oocyte maturation by activating genes that function in the meiotic cell cycle, is constitutively activated in cancer, and is necessary to maintain NAD^+ and ATP levels.

In the ER, the UPR^{ER} involves three stress arms regulated by the TFs, XBP1, ATF6, and ATF4, that bind to specific *cis*-elements for these ER-stress-responsive arms. XBP1 is activated by the transmembrane endoribonuclease IRE1, which is a transmembrane protein with kinase and endoribonuclease (RNase) activity that senses misfolding in the ER directly, leading to autophosphorylation, oligomerization, and acquisition of RNase activity. These events allow active IRE1 to cleave *XBP1* mRNA, generating a spliced transcript (*XBP1s*) that encodes XBP1, which induces the transcription of UPR target genes. ER stress also promotes the relocalization of ATF6 from the ER membrane to the Golgi apparatus, where it is cleaved by the proteases SP1 and SP2, generating a cytosolic fragment of ATF6 that translocates to the nucleus to direct transcription of a complementary set of UPR genes. Together, XBP1 and ATF6 induce the expression of genes involved in protein folding, ER-associated protein degradation, and lipid metabolism pathways. A third ER transmembrane protein, PERK, also induced by ER stress, promotes translation of the TF ATF4 by phosphorylating the translation initiation factor eIF2α. Under these conditions, ATF4 mRNA is preferentially translated, leading to selective expression of the proapoptotic TF CHOP, which elicits apoptosis in cells in which ER stress is not resolved, presumably to remove damaged cells from the population.

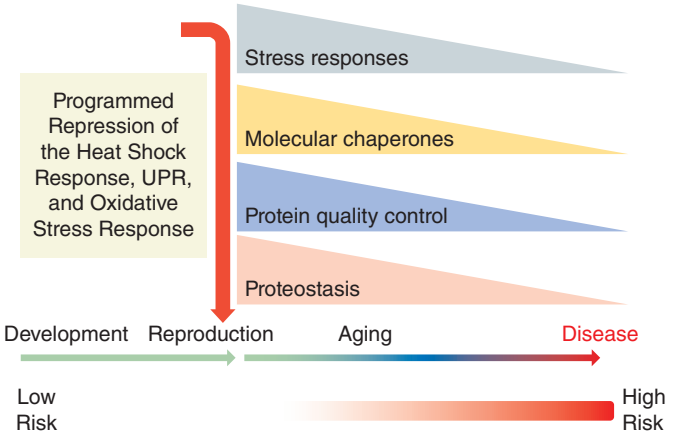


FIGURE 491-3 Aging and protein folding diseases. Aging is the major risk factor for degenerative diseases. Cell stress responses (heat shock response and the unfolded protein responses in the endoplasmic reticulum and mitochondria) decline at reproductive maturity in studies from *Caenorhabditis elegans* and prevent adaptive and protective increased expression of molecular chaperones to prevent protein misfolding. UPR, unfolded protein response.

For mitochondria, the UPR^{mito} response involves ATFS1, which contains a mitochondrial targeting sequence and a nuclear localization signal. Under normal cellular conditions, ATFS1 is imported into mitochondria and degraded, but upon mitochondrial stress, ATFS1 is directed only to the nucleus to regulate transcription of genes encoding mitochondrial chaperones, mitochondrial import machinery, and glycolysis. In mammals, the UPR^{mito} is regulated by ATF5, which corresponds to ATFS-1 in *Caenorhabditis elegans*.

In metazoans, the integration of stress survival strategies includes the antioxidant factor SKN-1/NRF2, the insulin-signaling factor DAF-16/FOXO, and the tissue identity factor PHA-4/FOXA. Oxidative and xenobiotic stresses activate OxR, which controls the expression of redox-regulatory proteins and components of protein degradative pathways mediated in mammals by NRF1/NFE2L1 and NRF2/NFE2L2, which corresponds to SKN-1 in *C. elegans*. NRF1 is an ER-resident factor that undergoes regulated proteolytic cleavage upon activation to control expression of genes encoding subunits of the proteasome and the UPS. NRF2 in the cytoplasm is negatively regulated by the redox-sensitive ubiquitin ligase KEAP-1; consequently, inactivation of KEAP-1 by oxidative and electrophilic stress leads to stabilization and nuclear translocation of NRF2, which, in turn, induces the expression of antioxidant proteins and detoxification enzymes.

ORGANISMAL PROTEOSTASIS IN AGING AND DISEASE

Much of our understanding on protein quality control mechanisms has come from in vitro studies with purified molecular chaperones or components of the UPS, complemented with cell extracts and cell-based assays using yeast or mammalian cells grown in tissue culture. A common theme that emerges from these studies is that of hormesis, in which transient bouts of activation of the HSR, UPR^{ER}, or UPR mito improves lifespan and organismal resilience but chronic activation is detrimental.

The importance of these pathways is further highlighted by studies suggesting neuronal coordination of stress responses at the level of the organism. When neuronal mechanisms fail, the HSR reverts to cell-autonomous control. At the organismal level, however, the HSR, UPR^{ER}, and the UPR mito in *C. elegans* are regulated by cell-nonautonomous control through neuronal signaling. When neuronal signaling is impaired, the HSR reverts to cell-autonomous control. Neuronal signaling also regulates the UPR mito with disruption of mitochondrial function in *C. elegans* neurons activating the UPR mito in nonneuronal tissues, supporting a role for a mitokine signal. Perturbation of the mitochondrial electron transfer chain (ETC) was shown to increase life span in both invertebrates and rodents through the activation of the UPR mito. The response to mitochondrial dysfunction in *C. elegans* depends upon the severity of mitochondrial impairment with a mild reduction of ETC having hormetic effects on organismal stress resilience, proteostasis, and longevity by resetting the cytoplasmic

HSR through HSF-1, independent of ATFS-1 and the UPR mito. Mild perturbation of the ETC in *Drosophila* muscle also has systemic benefits on organismal health and life span involving the insulin signaling. Communication between neurons also regulates the UPR^{ER} in peripheral tissues of *C. elegans*. During infection of *C. elegans* by pathogens, induction of the UPR^{ER} in nonneuronal tissues is mediated by sensory neurons, suggesting an organismal stress response. Cell-nonautonomous regulation of the UPR^{ER} has also been observed in mice, where overexpression of active XBP1 in pro-opiomelanocortin neurons activates the UPR^{ER} in the liver.

Other forms of intertissue communication that regulate proteostasis with beneficial effects on organismal health include: cholinergic signaling across the synaptic junction to enhance or inhibit HSF-1-regulated proteostasis in the muscle cells of *C. elegans;* transcellular chaperone signaling between somatic tissues or between somatic tissues and neurons of *C. elegans* to regulate the expression of HSP90 in receiving tissues via the tissue code factor PHA4/FOXA, protection of neurons and glial cells from elevated temperature-induced death by overexpression of small HSPs in *Drosophila* flight motor muscle cells, enhancing proteostasis in *C. elegans* muscle cells by elevated expression of DAF16/FOXO in the intestine, and that overexpression of dFOXO/4E-BP in *Drosophila* muscle influences proteostasis in retina, brain, and adipose tissues to delay the age-dependent accumulation of protein aggregates.

Cell stress responses and proteostasis decline in aging. Insights on the relationship between proteostasis, cell stress, and aging have come primarily from *C. elegans* with support from other invertebrate and vertebrate model systems and human cells. A set of endogenous metastable proteins that exhibit temperature-sensitive properties were shown to misfold in *C. elegans* at the permissive temperature during aging, which was associated with a decline in the HSR. The decline of proteostasis in *C. elegans* aging is regulated via cell-nonautonomous control involving germline stem cells that initiate the programmed repression of the organismal HSR resulting in the loss of stress resilience and age-associated protein aggregation. This is regulated at reproductive maturity by an epigenetic switch involving the timed placement of repressive H3K27me3 chromatin marks at the heat shock genes, causing chromatin inaccessibility for HSF-1. This age-dependent decline in the HSR can be reversed either by blocking the signal from germline stem cell signal(s) or preventing the epigenetic repressive marks. The relationship between reproduction and inducibility of the HSR observed in animals at reproductive maturity suggests that the age-associated events of cellular failure and loss of tissue robustness during aging are not random processes but, rather, highly regulated, perhaps to ensure that somatic tissues are programmed to decline after reproduction, consistent with the germline soma theory of aging.

Proteostasis is one of the pillars of gerontologic biology, which, together with genomic instability, telomere attrition, epigenetic alterations, deregulated nutrient sensing, mitochondrial dysfunction, cellular senescence, stem cell exhaustion, and altered intercellular communication, provides a mechanistic basis for the biology of aging. The programmed decline of proteostasis in early adulthood would suggest that failure in protein quality control would have negative consequences on the other key elements of gerontologic biology. Whether proteostasis collapse is the first to fail or among the earliest events to fail in aging, it is consistent with the very large number of human degenerative diseases in aging associated with protein misfolding.

PROPERTIES OF PROTEIN FOLDING DISEASES

The complexity that arises with protein folding diseases is that all tissues are at risk and essentially all proteins are at risk for misfolding. Added to this is the effect of aging and that each protein folding disease exhibits a highly variable age of onset for pathology. There is additional complexity in classification—whether to organize folding diseases by tissues, i.e., muscle proteinopathies or neurodegenerative diseases, according to the specific protein that misfolds such as α_1 antitrypsin (AAT) deficiency, or by the biophysical nature of the aggregate species in systemic amyloidoses.

Disorders in which a specific mutation leads to protein misfolding or the formation of a specific insoluble protein aggregates likely represent only the tip of the iceberg of protein folding disorders. Mutations in aggregation-prone proteins coupled with changes in the cellular environment and decline in capacity and robustness of the PN in aging promote protein misfolding and aggregation in affected tissues. Once aggregation has initiated, this leads to further impairment in protein quality control pathways, causing further collateral damage and aggregation of other at-risk proteins. Such a mechanism may only manifest clinically after a seemingly random systemic stress like pneumonia, large bone fractures, or ischemic vascular events, possibly explaining the rapid (1–2 years) accumulation of age-related morbidities in the year following the first event. As such, the age-related decline in the function of any of the components of the PN could underlie the compounding multiple morbidity that limits health span and life span in many elderly individuals. Within this framework, it is useful to discuss some of the better understood mechanisms of proteostasis dysfunction that have been causally linked to diseases in humans.

DISORDERS THAT ENHANCE MISFOLDING AND CAUSE PREMATURE DEGRADATION (CYSTIC FIBROSIS)

Cystic fibrosis (CF) is a recessive disorder caused by mutations in both alleles of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene that encodes a multidomain membrane-spanning chloride ion channel protein. Thousands of mutations in *CFTR* have been identified that affect *CFTR* biosynthesis, folding, trafficking, and function, leading to chronic obstructive lung disease, intestinal obstruction, liver dysfunction, exocrine and endocrine pancreatic dysfunction, and male infertility. CF is a folding disease due to its recognition by the PN as misfolded protein. The most prominent mutation is deletion of phenylalanine 508 (F508del), present in ~90% of CF patients. Mutant ΔF508 retains partial channel function, but because it is recognized as misfolded in the ER and the cytoplasm, it is marked with ubiquitin for degradation by the ubiquitin proteasome system. Small molecules that affect the conformation and function of mutant ΔF508 channel function can result in substantially improved outcomes in patients.

DISORDERS THAT INDUCE TOXIC AGGREGATES AND LOSS OF FUNCTION (AAT DEFICIENCY)

AAT deficiency (AATD) is a co-dominant inherited disease with an increased risk of chronic obstructive pulmonary disease (COPD), liver disease, and vascular inflammation. Pulmonary problems are more frequent in adults, whereas liver and skin problems may occur in adults and children. AAT is encoded by the *SERPINA1* gene, secreted into the circulation by the liver, and responsible for inactivating endogenous proteases, particularly those secreted by neutrophils and other inflammatory cells in the lung. Patients with AATD harbor mutations in *SERPINA1* that cause misfolding in the ER. The two major phenotypes resulting from this abnormality highlight the diverse consequences of misfolding on different cells and organs. In the liver, misfolding of the mutant protein results in the formation of toxic aggregates and hepatocyte death, manifest as liver injury and eventually cirrhosis—a gain-of-function toxicity. In the lung, the failure to secrete sufficient AAT causes unchecked proteolytic damage to the delicate architecture of the alveolus, a process that is markedly worsened when neutrophils are recruited to the lung in response to cigarette smoking. This loss-of-function phenotype manifests pathologically as emphysema and clinically as COPD.

INTERACTIONS WITH PN COMPONENTS THAT CHANGE CONFORMATION, STABILITY, OR FUNCTION (CANCER)

Mutations in the tumor suppressor p53 are among the most common mutations observed in patients with cancer. Deletion of p53 combined with overexpression of an oncogene is sufficient to drive metastatic

cancer formation in mice, causally linking p53 mutations with cancer. Normally, p53 functions as a transcription factor that suppresses the transcription of genes involved in apoptosis resistance. While myriad mutations in p53 have been described, some result in an alternate conformation that interacts with different HSP70 chaperones within the PN. Binding of the mutant p53 protein to these chaperones affects the DNA binding property necessary for its tumor-suppressor function and facilitates binding to other domains, resulting in changes in gene expression that protect malignant cells from apoptosis.

STRONGLY ENHANCED AGGREGATION PROPENSITY AND AMYLOID FORMATION (ALZHEIMER'S DISEASE, PARKINSON'S DISEASE, AMYOTROPHIC LATERAL SCLEROSIS, HUNTINGTON'S DISEASE, TYPE 2 DIABETES MELLITUS)

In some individuals, native or mutant proteins include sequence motifs that promote an alternate highly ordered aggregation state when the cellular environment is altered and in aging. The most common of these motifs are the beta-pleated sheets, which, when exposed to the solvent environment of the cell, easily bind to one another in an iterative process that can accommodate many thousands of molecules that form insoluble cross-beta sheet amyloid species. Broadly, these intracellular aggregates are classified as oligomers (2–24 molecules), protofibrils (rods 4–11 nm wide and 200 nm long), and amyloid fibrils with a similar width to protofibrils but microns in length. While the formation of oligomers is thermodynamically unfavorable, polymerization is favorable, causing aggregates to seed slowly but grow exponentially. In some cases, for example, Huntington's disease, familial forms of Alzheimer's disease, and ALS, aggregation is accelerated by mutations. However, in many cases, the aggregates contain other cellular proteins that share biophysical properties of aggregation propensity or reflect dysfunction in the PN that facilitates their seeding or propagation (see below). While in most instances, damage caused by protein aggregates is localized to the cells in which they form, as occurs with islet amyloid peptide in some patients with type 2 diabetes, amyloidogenic proteins associated with neurodegenerative diseases have been shown to "spread" between cells. Damage to neurons by aggregates in Alzheimer's disease can elicit a local inflammatory response by resident immune cells in the brain, both of which contribute to pathology. Much effort has been directed toward the detection of aggregates and amyloid and the development of small molecules or antibodies that block further growth or the enhancement of cellular activities of the PN to suppress protein misfolding.

SECRETED AGGREGATED AND AMYLOID SPECIES CAUSING SYSTEMIC AMYLOIDOSIS

In patients with systemic amyloidosis, the secretion of large amounts of aggregation-prone proteins results in the deposition of aggregates in many tissues. These proteins can include immunoglobulins secreted from plasma cells in patients with systemic inflammation or multiple myeloma or other aggregation-prone proteins including transthyretin. Similar to other aggregate-induced diseases, mutations in transthyretin that facilitate polymerization are associated with an increased risk of developing systemic amyloidosis with advancing age. These aggregates induce cellular toxicity, inflammation, and matrix reorganization that interfere with function in an organ-specific manner. Deposition of amyloid produces stiffness where there should be flexibility, creates barriers where there should be free flow, and distorts size where there should be fit. The stiffness is particularly damaging to the heart, lung, and blood vessels and both smooth and skeletal muscle. The barrier effect can result in malabsorption in the gastrointestinal tract and glomerular dysfunction, cardiac and peripheral nerve conduction defects, and limitation of joint range of motion.

NATIVE PROTEINS PRONE TO AGGREGATE WHEN THE CELLULAR ENVIRONMENT IS ALTERED BY STRESS AND AGING

While well-defined genetic abnormalities have been essential in elucidating the molecular mechanisms that underlie the formation of protein aggregates and causally linking them to disease, many, if not most, clinical diseases associated with the formation of protein aggregates develop in patients without identified mutations. In these patients, a decline in the chaperone and quality control mechanisms of the PN allows exposure of aggregation-prone domains of normal proteins to the solvent environment of the cell. Once seeded, these protein aggregates can expand rapidly to induce local or systemic injury. The decline in function of the PN that allows these aggregates to form might develop gradually with advancing age or might occur suddenly in response to an age-triggered biologic program, as occurs in *C. elegans*.

INFECTIOUS DISEASES AND IMBALANCED CELL STRESS RESPONSES IN AGING

A model in which the function of the PN is reduced in aging might explain the disproportionate morbidity and mortality in older individuals exposed to systemic stress. While these stressors include infections, surgical or accidental trauma, sepsis, and myocardial infarction, among others, pneumonia, the most common cause of death from an infectious disease in the United States, provides an illustrative example. As was evident during the COVID-19 pandemic, pneumonia morbidity and mortality disproportionately affect the elderly. Viral pneumonias, including those caused by influenza viruses and SAR-CoV-2, are primarily localized to the lung, where they activate a local and systemic inflammatory response and denude the alveolar lining. The resulting hypoxemia and systemic inflammatory response injures distant organs independent of viral injury. Impaired function of the PN during the stress might allow seeding of tissues with toxic aggregates with long-term consequences. Repair of the damaged lung and distant organs represents a major challenge to proteostasis that might be overcome in younger individuals but fail in those who are older with poor stress resilience. This loss of proteostasis resilience necessary to limit damage and allow repair could explain clinical observations in pneumonia survivors who develop persistent lung injury, skeletal muscle dysfunction impairing mobility, chronic kidney disease, cognitive dysfunction and dementia, and an increased risk of ischemic cardiovascular events in the year after hospital discharge.

492 Novel Approaches to Diseases of Unknown Etiology

David Adams, Camilo Toro, Joseph Loscalzo

THE UNDIAGNOSED DISEASE STATE

The term *disease*, etymologically meaning "lack of ease" or the presence of discomfort, is defined as an abnormal state that negatively affects the structure or function of all or part of an organism and that is not due to any immediate external injury. When referring to a person experiencing a disease, the word *patient* is used in its original, meaning "the one who endures suffering." These terms are well suited when referring to patients with undiagnosed diseases. A patient with an undiagnosed disease is one for whom a medical diagnosis is not discerned after reasonable efforts utilizing established methods and procedures. Multiple factors may contribute to a failure to reach a diagnosis (Table 492-1). Patients who are affected by an undiagnosed disease for a protracted period of time can be said to be in an undiagnosed disease state.

THE MEANING AND CONTEXT OF A DIAGNOSIS

A diagnosis often entails hierarchical levels of information specificity with varying levels of relevance to the users (consumers) of such information, i.e., patients and their families, health care providers, government health care agencies, insurers, epidemiologists, genetic counselors, pharmacologists, biologists, etc. As an example, a diagnosis of Parkinson's disease in an adult is based on the progressive emergence of signs and symptoms of bradykinesia, rigidity, asymmetric rest tremor, and postural instability (clinical diagnosis), which are typically responsive to the administration of L-dopa (a therapeutic response biomarker). Together, these are cardinal features of striatonigral degeneration (a mechanistic diagnosis), a process associated with neuronal α-synuclein deposition and Lewy body pathology (histopathologic diagnosis) often based on a genetic susceptibility conferred by mutations in genes such as synuclein (*SYNCA*, a molecular diagnosis) and likely influenced by environmental exposures (e.g., manganese or other neurotoxins).

With ongoing advancements in medical science and technology, the standard for what constitutes a reasonable diagnosis continues to evolve toward higher levels of specificity. Efforts to adopt the principles of precision medicine include a growing emphasis on the context of disease within the genetic repertoire, environment, social factors, medical history, nutrition, and the microbiome of any given individual. Examples include cancer susceptibility, genetically determined idiosyncratic reactions to medications, and unique pathogen susceptibilities in patients with certain immune deficiencies.

TABLE 492-1 Factors Contributing to the Presence of an Undiagnosed Disease

FACTOR	EXAMPLE
Misleading information	False-negative and false-positive test results
Rare disorder	Many inherited disorders have only been identified in a few individuals. For example, sialuria, a well-understood disorder of sialic acid metabolism, has been reported in 10 individuals (OMIM 269921).
Unusual causes of common diseases, including atypical course of illness	Insulin-dependent diabetes mellitus may be the presenting feature for the relatively rare autoimmune polyendocrinopathy syndrome, type I (OMIM 240300).
Presence of multiple disorders (blended phenotypes)	For an example, see PubMed ID 24863970.
Lack of characteristic symptoms of known disease	Diseases are commonly ascertained via cardinal signs or symptoms leading to incomplete ascertainment of all possible disease presentations. For instance, not all persons with Marfan's syndrome are tall relative to other family members. For progressive diseases, pathognomic signs and symptoms may be missing in early stages of disease.
New disease	No prior knowledge or record of such disease
Incorrect affected status assignments in family history	A heritable disorder may be inappropriately excluded if family history information is incorrect.
Primary disease manifestations obscured by other factors	Maladaptive behavior, medication effects, and secondary disease manifestations may obscure signs and symptoms of a primary disorder.
Disease not expected in region or population	Cystic fibrosis in persons of African ancestry, sickle cell disease in persons of northern European ancestry; infectious agents with marked geographical incidence patterns
Diseases thought to be eradicated	Poliomyelitis
Diseases occurring in unexpected time of life	Parkinson's disease in children, lysosomal storage disease in adults
Malingering	Feigned disease features intended to achieve secondary gain (Munchausen syndrome)
Rare disease mechanisms	Transmitted or sporadic prion disease, unusual zoonotic diseases

Abbreviation: OMIM, Online Mendelian Inheritance in Man.

UNDIAGNOSED RARE DISEASES

Most undiagnosed diseases are rare. While individual rare diseases have a low prevalence by definition, they are numerous in aggregate. It is estimated that >6000 rare diseases affect millions of people throughout the world. Many rare diseases have a genetic basis and onset in childhood. As the cloud of uncertainty inherent in the undiagnosed disease state is removed, new disease-specific counseling, therapies, resources, community engagement, and advocacy opportunities become possible.

THE EFFECT OF THE UNDIAGNOSED DISEASE STATE ON THE PATIENT

Patients with an undiagnosed disease are frequently driven to understand the basic nature of their ailment (what, when, where, how, etc.). Individuals, families, physicians, and society, however, might have a wide range of tolerance to the uncertainties associated with the undiagnosed disease state. Being undiagnosed has profound detrimental effects. Patients can go undiagnosed for decades, leading to personal and family uncertainty, high levels of stress, decreased productivity, limited accessibility to disease-specific counseling and resources, decreased quality of life, and excess utilization of medical services.

APPROACH TO CHALLENGING DISEASES OF UNKNOWN ETIOLOGY

Approaches to a patient with an undiagnosed disease can be separated into two categories. The first is a new assessment by a consultant, new provider, or diagnostic referral center. The second is periodic reassessment by an existing provider for a patient who remains undiagnosed.

COMPREHENSIVE DATA COLLECTION

A potentially time consuming but critical initial step is the aggregation of all available medical data. Essential records are listed in Table 492-2.

TABLE 492-2 Essential Records for Undiagnosed Disease Patients

1. Any narrative summaries that detail the course of the illness
2. Copies of original test results with names, dates, testing circumstances, normal ranges, and test facility information
3. Electronic copies of imaging studies
4. Consultation notes
5. Hospitalization intake and discharge summaries
6. Accurate family history accounts and family relations

Optional but potentially useful records include:

1. Photographs and/or videos of disease manifestations
2. Longitudinal data (growth charts, symptom logs, serial lab measurements)
3. Data or specimens that could be reanalyzed, including pathology specimens and genomic sequencing of raw data

The overall goal of data collection is a full understanding of the course of the disease and a verification of critical data elements used for diagnostic decision-making. Incorrect or partial second-hand accounts of prior test results contribute substantively to incorrect or missed diagnoses.

Analysis of the collected data allows for reconstruction of the process by which previous disease presentation, diagnostic thought processes, and test interpretation led to the current understanding of a patient's illness. Unintentional obfuscation of the history and findings can result from missing records, incomplete recall by the patient and fragmentation, and propagation of information (and misinformation) in the medical record. Optimally, the presence and character of key features of the illness will be reinforced by perspectives derived from multiple evaluations.

VALIDATION OF SUBJECTIVE AND OBJECTIVE FINDINGS

Teasing apart the layers of a patient's presentation often uncovers a variety of adaptive (and maladaptive) coping strategies. Some are idiosyncratic to the disease state (e.g., sun avoidance in a patient with xeroderma pigmentosum), whereas others are driven by psychosocial factors and could become primary drivers of the phenotype. It is important to consider, however, that patients believed to have "functional" or "somatoform" disorders, e.g., nonepileptic events (pseudo seizures), frequently have concurrent bona fide epileptic events. Careful consideration of clinical phenomenology and associated findings on physical examination and ancillary investigations may provide clarity, affirmation, and effective redirection. Distinct clinical, radiographic, and laboratory abnormalities provide entry points to the generation of a differential diagnosis and could become effective biomarkers of disease progression and response to interventions.

Testing Strategies and New Technology The historical exclusion of a diagnostic hypothesis may be based on testing that is no longer state of the art. For example, congenital disorders of glycosylation (CDG) were historically diagnosed using transferrin isoelectric focusing. It was subsequently found that the diagnosis of many CDG types required mass spectrometric and molecular approaches. The initial assessment of a patient with an undiagnosed disease should include a reassessment of the diagnostic logic and data used in past decision-making. In the absence of concrete diagnostic leads, the use of broad scope screening tools may prove beneficial in generating meaningful diagnostic hypotheses (Table 492-3). In some cases, newer testing options may be difficult to obtain and/or be costly. Prior probability of disease and available resources will factor in determining whether new diagnostic testing is practical.

TABLE 492-3 Clinically Available Tests with Notable Utility for Undiagnosed Cases

TEST	TARGET PHENOTYPES	RATIONALE
Single nucleotide polymorphism microarray and/or karyotype	Dysmorphic features, cognitive impairment, neurodevelopmental disorders	Genomic structure abnormalities may be missed by other testing
Exome or genome sequencing	Any undiagnosed disease that is chronic and not clearly acquired	Tests a broad range of potentially unconsidered diagnostic entities
Lysosomal storage diseases (LSDs), molecular or enzymatic tests. urine organic acids, urinary glycosaminoglycans (GAGs), oxysterols	Progressive neurologic disorders, psychiatric disorders	Some LSDs have nonspecific presentations, and adult-onset cases are often missed
Congenital disorders of glycosylation, Apo CIII and N-glycan mass spectrometry	Pediatric-onset disorders, cognitive impairment, neurologic phenotypes	Large group of disorders; phenotypes for many still being characterized.
Biochemical disorders, ammonia, serum polyols, urine purines and pyrimidines, plasma amino acids, very-long-chain fatty acids	Neurologic phenotypes, especially with waxing and waning course, selective speech involvement or patients with unusual self-selected diets	Metabolic disorders may have nonspecific symptoms, and adult-onset cases are often missed
Mitochondrial sequencing and mitochondrial depletion studies; biochemical screening with serum lactate, blood pyruvate, plasma amino acids, and GDF-15	Complex multisystem disorders with neurometabolic, endocrine, and gastrointestinal symptoms, muscle dysfunction, and waxing and waning or progressive course	Large group of disorders with a wide range of presentations; yield is improved by studies in affected tissue (e.g., liver or muscle)
Cerebrospinal fluid (CSF) studies including amino acids (AAs), lactate, pterins, methyltetrahydrofolate (MTHF), or special CSF flow studies	Synthetic neurotransmitter defects in patients with unexplained fluctuating encephalopathy/movement disorders or patients with atypical neuroinflammatory syndromes	Patterns of profiles point to particular enzymatic deficits in neurotransmitter synthesis or characterization of unique immunologic profiles of inflammatory central nervous system diseases

Molecular Approaches, Including Genomics The availability and variety of clinical molecular modalities have transformed diagnostic testing in many settings. These advances have arisen from both testing scope, e.g., exome-wide, genome-wide, and transcriptome (RNA sequencing [RNA-Seq]) sequencing, and new medical knowledge, e.g., new disease-gene associations and molecular interaction networking (network medicine). Complementary screening tools, such as metabolomics, show diagnostic promise, particularly when combined with sequencing data to generate a fuller picture of disease manifestations. Simultaneous consideration of multiple data types can provide a means of appreciating overlapping and reinforcing evidence, with the potential to inform both hypothesis-driven and agnostic approaches to diagnosis.

HYPOTHESIS-DRIVEN MOLECULAR TESTING Hypothesis-driven testing implies that a defined set of heritable (or potentially heritable) disorders is the principal impetus for testing. Selection of a targeted gene sequencing panel, possibly augmented with structural variant detection technologies, may allow for improved sensitivity, lower cost, and fewer unrelated (secondary) findings relative to full exome or genome sequencing studies. In the setting of an initial undiagnosed disease evaluation, prior sequencing panels may not include recently discovered genes. Testing with an updated panel or targeted sequencing of a newer gene is an option for consideration. In some cases, sequencing panels are generated by selective reporting of relevant genes within an exome data set. In such cases, it may be possible to expand the analyses to new genes of interest without additional sequencing.

AGNOSTIC MOLECULAR TESTING Agnostic testing typically uses data from exome or genome sequencing and considers all possible diagnoses, even those with a low pretest probability of being present. This approach can also generate hypotheses for potentially new disease-gene associations. Analysis of the sequencing data typically includes an unrestricted search throughout the entire human genome or exome space. DNA sequence variants with potential medical relevance are identified first by bioinformatic characteristics, including known association with disease, predicted importance for protein function, interspecies conservation, population frequency, and an evolving list of other factors. The list of candidate variants is then subject to expert review (i.e., curation). The interpretation of test results in this setting is highly influenced by both the adequacy of communication between the clinical and testing teams and the information content of the data sources used to annotate each of the thousands of variants generated in the course of sequencing.

There is a rapid proliferation of new testing platforms and analytical tools with the potential to contribute to solving undiagnosed diseases, but it remains challenging to judge their broad utility. While awaiting for systematic validation and practice standards, novel techniques may be considered in special cases where a diagnostic hypothesis is closely

TABLE 492-4 Emerging or Special Testing Strategies and Related Diagnostic Questions

TESTING STRATEGY	RELATED DIAGNOSTIC QUESTION	AVAILABLE CLINICALLY[a]
Transcriptomics, RNA-Seq	Relevance of splice, regulatory, and other noncoding variants; correlated changes in gene expression within pathways	No
Metabolomics	Hypothesis generation via nontargeted approaches, correlated pathway changes, correlation with molecular findings	Yes
Epigenetics	Diseases known or suspected to be caused by methylation or parent-of-origin effects	Some
Transcriptional profiling	Search for profile particular to certain disease states, e.g., interferon inducible genes panels (interferon signature) in certain autoinflammatory disorders	Some
Specialized, disease-specific testing	Prion-related diseases, metabolic diseases, and many other assays	Some
Functional validation	Model organisms, cell biology, and other approaches to validating a hypothesized gene-disease association	No
Metagenomics	Search for molecular fingerprints of other organisms (e.g., infectious agents) within human samples	Yes
Long-read sequencing technology	Accurate resolution of low-complexity regions of the human genome (repeat expansion disorders) and complex genome structural rearrangements	No
Deep sequencing	Accurate resolution of low levels of mosaicism	Some

[a]Available clinical tests are often a small subset of approaches available via research collaboration. Clinical testing offerings are evolving rapidly and should be reassessed periodically.

aligned with the type of data generated by a specific testing strategy (Table 492-4).

PERIODIC REEVALUATION

The cornerstone for the care of a patient in an undiagnosed disease state is a plan for periodic reevaluation until a diagnosis is achieved. The Undiagnosed Diseases Network, a 10-year National Institutes of Health–sponsored national program specifically designed to evaluate undiagnosed patients (with several international counterparts), reported a diagnostic rate of ~30%. This finding illustrates the fact that many affected individuals remain in an undiagnosed state for a protracted period of time. For a medical provider, the care of an undiagnosed patient includes a program for symptomatic care, support related to the undiagnosed state itself, and plans for a regular reevaluation strategy seeking new insights into the diagnosis by following its time trajectory. Reevaluation is guided by emerging knowledge in the field, disease progression, and the development of new signs and symptoms. The appearance of a similar disease in a sibling or close relative may provide critical insight. Communication with the patient is an essential component. Many individuals with an undiagnosed disease report feeling abandoned by their providers once diagnostic ideas have been exhausted. Providers themselves may feel discouraged in being unable to provide a diagnosis. The institution and discussion of a well-defined plan for periodic reassessment and communication can help reinforce the patient-provider relationship and set reasonable expectations.

Reevaluation of Differential Diagnosis The key to success for a planned reevaluation visit is preparation. The problem and differential diagnosis lists should be subject to careful, evidence-based review. New or resolved clinical features may add or remove diagnostic considerations. The passage of time may result in the emergence of distinct new phenotypic manifestations that serve as new clues in the formulation of a definite diagnosis. Special consideration should be given to the effects of reaching maturity and aging. The establishment of a phenotype as being static versus progressive has prognostic value. Careful documentation of the rationale for including or excluding individual disorders will streamline the process for both future reevaluations and the need for consultants. Concurrent development of common diseases should be thoughtfully considered as a possible component of the primary undiagnosed condition. For example, insulin-dependent diabetes mellitus could be a feature of the rare autoimmune polyendocrinopathy associated with mutations in the autoimmune regulator gene *AIRE*.

New Literature Keeping abreast of current literature is an important and challenging activity for all medical providers as the body of medical knowledge continues to grow exponentially. For undiagnosed diseases, newly reported disorders and disease-gene associations are an important source of diagnostic resolution. Literature search tools such as PubMed can be augmented by online resources that connect clinical signs and symptoms (phenotypes) to disorders. For instance, using the search terms "cardiomyopathy arthropathy diabetes hyperpigmentation" in the Online Mendelian Inheritance in Man website (*https://omim.org*) produces a list of disorders that includes hemochromatosis. In the context of an undiagnosed disease, this type of phenotype-driven approach can be used to search for new, relevant publications and disorders. Tools that automate such searches continue to be developed in both open-source and commercial settings. The success of these approaches is augmented by iterative application, ideally as part of formal, periodic reevaluation of the undiagnosed patient.

GENOMICS

The use of medical testing based on the determination of DNA sequence and structure (sometimes referred to as molecular testing) has proliferated in recent years. A wide variety of approaches are available to the clinician, from single-gene sequencing to exome or genome sequencing. Many reviews of this topic are available (see Adams and Eng, 2018, in "Further Reading"). Consultation with colleagues trained in genetics can be useful when developing an optimal testing approach.

In some cases, genetic testing results may already exist in the medical record during the initial evaluation of an undiagnosed patient. This is increasingly true for younger patients; exome and genome sequencing are being used earlier, and with increasing frequency, for complex diagnostic challenges. Reanalysis of previously obtained exome and genome data should start with consideration of both the age and quality of the study and the reported patient phenotype at the time of the study report. For sequence results generated in a clinical laboratory, a discussion between the provider and the laboratory director often answers important questions about recommended next steps. The discussion should touch on how technologic advances have affected the utility of the older data and whether the laboratory offers reanalysis of the data. At a minimum, the provider, the testing laboratory, or an identified subspecialist should review previously reported DNA variants of unknown significance considering interval reports about the gene in question. More advanced reanalysis strategies are emerging and may be offered by the testing laboratory.

Some laboratories offer release of raw DNA sequencing data to their patients on request. The utility of raw data varies and depends on the identification of bioinformatics collaborators willing to reanalyze the data. Sequencing data obtained as part of a research study may not be suitable for clinical diagnostic purposes. In practice, raw and research-generated sequencing data are most useful when a collaborating researcher can be identified.

When considering a new sequencing test, the inclusion of the parents and siblings of the proband has the potential to provide enormous value in some situations. Discussion of an optimal approach with an expert colleague or the testing laboratory is encouraged.

EXPOSOME

In many cases, a detailed occupational and environmental exposure history should be obtained. Some rare disease phenotypes are pathognomonic of specific toxicant exposures (e.g., mesothelioma

and asbestos exposure, clear cell adenocarcinoma of the vagina and intrauterine diethylstilbestrol (DES) exposure, chloracne and exposure to halogenated aromatic hydrocarbons). For the most part, however, chemical toxicant exposures do not produce unique phenotypes. Rather, chemical exposures operate in conjunction with lifestyle factors (e.g., smoking, alcohol intake, and nutritional status), differential host susceptibility (determined by age, sex, comorbidities, genetics, etc.), and nonchemical stressors (e.g., psychosocial stress) to produce (1) common, readily diagnosed medical diseases (e.g., asthma); (2) unusual or nonspecific phenotypes (e.g., erethism and metallic mercury exposure); or (3) atypical presentations of otherwise well-characterized disease states, initially considered an undiagnosed disease (e.g., manganese-induced parkinsonism). The nonspecificity typical of chemical-induced disease risk is further complicated by lack of exposure biomarkers for many common environmental toxicants (e.g., volatile organics), the short half-life of some contaminants (e.g., arsenic), and the possibility of decades long latency between exposure and disease onset (e.g., chemical carcinogenesis or dietary exposures to specific biochemical risk factors for atherothrombosis). In addition, we live in an era in which new chemicals are introduced into consumer products and the environment at a pace well beyond our capacity to characterize their toxicity. Within this context, one of the most powerful tools for ascertaining chemical-related disease risk is a systematic exposure history. Although there are no standardized instruments for this purpose, there are published guidelines to implement exposure assessments (Goldman and Peters, 1981; see "Further Reading" below). These include a multistep approach to exposure assessment including a job history; a review of exposures at work and at home or via hobbies and recreation; ascertainment of any temporal relationship of symptoms or disease onset to work, home, or recreational activities; and the food frequency questionnaire. If this screening identifies a potential exposure or exposures of concern with respect to patient symptoms and phenotype, a second step of evaluation involves a more detailed history to identify specific suspect agents, options for quantitative environmental exposure assessment (e.g., household tap water sampling, review of workplace Material Safety Data Sheets [MSDSs]) and biomonitoring, and etiologic plausibility for at least some aspects of the patient's phenotype.

The traditional approach to focused external exposure assessment proposed above does not, however, provide an integrated, quantitative measure of all exposures over the life course, an exposure characterization of particular interest for the risk of chronic diseases such as cancer or atherothrombosis. The exposome has been proposed as a promising means for capturing the totality of human exposure over a lifetime (analogous to the totality of genetic exposure assessed via genomic analyses), including not only external chemical or dietary/foodome (Barabasi et al., 2020; see "Further Reading" below) exposures but also internal (e.g., metabolic, hormonal, microbiome) influences and psychosocial factors. However, techniques for measuring the exposome are in relatively early stages of development, are limited by the substantial variability in human exposure experience, and have not yet been designed to capture complex combinations commonly encountered in environmental or occupational exposure settings (Peters et al., 2012; Wild, 2012; Brunekreef 2013; Barabasi et al., 2020; see "Further Reading" below). This important element of assessing patients with undiagnosed disease is, however, evolving rapidly and offers the promise of becoming a more formal part of the evaluation of many patients with undiagnosed disease.

ENGAGEMENT OF RESEARCH APPROACHES

Establishing a research collaboration for a patient with undiagnosed disease can be both challenging and rewarding. Time and effort resources are likely to limit this approach to a subset of patients with particularly compelling clinical presentations and a strong hypothesis about disease causation. The process must include early and detailed communication with the patient. Several approaches may be considered.

Leveraging Phenotypic and Genotypic Similarities For a patient with a rare or undiagnosed disease and distinct presenting features, finding similarly affected individuals adds substantial benefits. It can encourage research, provide a community for affected patients, and improve the chances of finding commonalities in pathogenesis and therapeutic strategies. Phenotypic aggregation may also allow the patient to connect with consortia invested in related medical presentations. Examples include organizations dedicated to the study of related diseases such as leukodystrophies, autoinflammatory disorders, and even undiagnosed diseases, NORD, the National Organization for Rare Disorders (*rarediseases.org*) can be a useful starting point. The Office of Rare Disease Research within the National Center for Advancing Translational Science supports consortia under the Rare Disease Clinical Research Network program. Building patient cohorts may also be based on specific biological mechanisms or pathways, for example, the United Mitochondrial Disease Foundation.

Data Sharing The proliferation of DNA sequencing technology and the subsequent generation of many DNA variants of unknown clinical significance have prompted the creation of data-sharing resources specifically designed to match similar cases submitted by clinicians and researchers around the world. For example, a clinical exome report may identify variants in a gene with a potential but unproven relationship to the patient's presenting illness. The clinician could enter the gene name into a gene-matching database, and if the same gene name had been already entered by a different submitter, the database would flag a match and send contact information to both submitters. The matching procedure has the potential to identify additional cases of an ultrarare or newly described condition, while avoiding the sharing of the patient's personal health information. Embellishments of this approach involve inclusion of phenotypic features, data entry by families, and specific details of sequence variants. Example systems include GeneMatcher, PhenomeCentral, and DECIPHER.

Collaboration Collaborations around undiagnosed disease patients may take many forms. Studies focusing on related medical conditions can sometimes be identified using the *https://clinicaltrials.gov* website, which lists many U.S. and non-U.S. clinical studies. Databases of clinical information (e.g., this textbook, GeneReviews) can be used to identify subject matter experts for related conditions. Such experts can be queried about ongoing studies. In some cases, a willingness to work with consenting families to provide biological specimens can open additional avenues for collaboration.

CHALLENGES

Data Portability Obtaining specimens, data, and records for a chronically undiagnosed patient can be time-consuming and challenging. Families may be charged fees for obtaining copies of old studies. Although continuing advances in record access are occurring, families should be encouraged to collect and maintain an updated collection of medical records. These should include copies of consultation notes, original laboratory results, and radiology studies (the latter preferably in electronic form). These record collections are useful for consultation, second opinions, and transitions between primary providers.

Managing Illness Behaviors, Expectations, and Secondary Manifestations Patients with undiagnosed diseases may present in any stage of the grieving process. Coping with uncertainty, loss of abilities, work, relationships, autonomy, and financial security compound the primary manifestation of the disease. Patients may have a wide range of expectations about the possible benefits of achieving a diagnosis, including successful therapy. Patients of reproductive age may find that their greatest uncertainty surrounds the potential heritability of their disorder, its effects on future reproductive decisions, and the potential risk it may represent to their children and living relatives. These factors may be equally or more disabling than the primary illness and require an individualized and multidisciplinary approach.

CONCLUSION

Chronically undiagnosed diseases present a complex challenge to patients, medical providers, and society at large. Development of a comprehensive plan for evaluation, reevaluation, and support requires a substantial investment of time and effort **(Fig. 492-1)**.

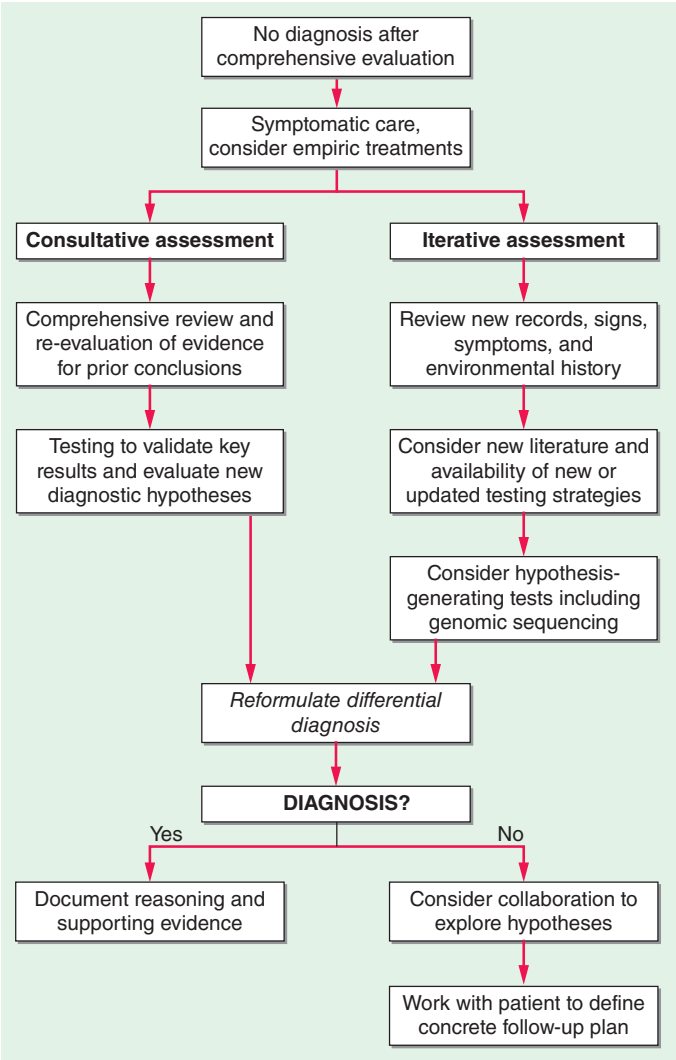

FIGURE 492-1 Approach to the patient with an undiagnosed disease.

Achieving an accurate diagnosis removes at least one level of uncertainty and allows for disease-specific counseling, therapies, resources, community engagement, and advocacy opportunities otherwise not afforded to undiagnosed patients.

clinical features of, 3233, 3668
arthropathy, 2848, 2871, 3233
cardiac, 1851, 1882, 1965, 3233
cutaneous, 391, 1816, 3233
diabetes mellitus, 3233
hepatic, 2549, 2628, 3233
hypogonadism, 3016, 3233
diagnosis of
CMR, 1851, 1859v
endomyocardial biopsy, 1965, 1965f
laboratory tests, 2550t, 3233–3234, 3233t
liver biopsy, 3234, A13
early interventions for, 3667t, 3668
environmental factors in, 3651
in females vs. males, 3651
hepatocellular carcinoma and, 643, A13
hereditary
clinical features of, 2628
diagnosis of, 2628
gene mutations in, 3230, 3230t, 3232
genetic testing for, 2549, 3667t
screening for, 3234f
pathophysiology of, 3232, 3232f
precirrhotic (early), 3230
prevalence of, 3231
prognosis of, 3235
screening for, 3234, 3234f
secondary. *See* Iron overload
treatment of, 1965, 3234
V. vulnificus infection in, 1310
Yersinia septicemia and, 1327

Hemodialysis
  access for
    arteriovenous grafts and fistulas, 2322, 2377–2379, 2377f
    catheters, 2377
    complications of, 2378
    history of, 2377
    physical examination in, 2377–2378, 2379v
    physiology and pathophysiology of, 2377
    preservation of, 2379
  for AKI, 2308
  bullous dermatosis of, 392
  for CKD, **2320,** 2322f
  in diabetes mellitus, 3124
  for drug- and toxin-induced acidosis, 363, S1
  for Fabry disease, 3258
  folate deficiency in, 773
  for hypercalcemia, 357, 723, 3184t, 3185
  for hyperkalemia, 355
  for hypermagnesemia, 3166
  oxalosis in, 2867
  pericarditis in, 2023
  for poisoning/drug overdose, 3589, 3590t, 3591t
  for pulmonary edema, 2255
  for rewarming, 3633, 3633t
Hemodynamic assessment
  calculation and normal values, 1861t, 2254t
  in cardiac catheterization, **1861**
  in cardiac tamponade, 1863t
  normal waveforms, 1862f
  in pericarditis, 1863t
  in restrictive cardiomyopathy, 1863t
  in shock, 2254t
  in STEMI, 2062, 2254t
  in valvular heart disease, 1861, 1862f
Hemoglobin (Hb), **755**
  age-related changes in, 433t
  developmental biology of, 755
  disorders of
    diagnosis of, 756–757
    hemoglobinopathies. *See* Hemoglobinopathies
    hereditary persistence of fetal hemoglobin, 755t, 756, 757t, 762t
    thalassemias. *See* Thalassemia syndromes
  elevated, 273, 438
  functions of, 755–756
  globin gene clusters, 755, 755f
  globin gene switching, 756
  high O_2 affinity, 765, 765t
  iron content of, 748t
  iron metabolism and, 748
  low O_2 affinity, 765, 765t
  in microcytic anemia, 751t
  normal, 432, 433t
  in pregnancy, 433t
  reduced, in cyanosis, 274
  structure of, 755
  testosterone therapy and, 3024
Hemoglobin A (HbA), 755, 757t
Hemoglobin A_{1c} (HbA_{1c}), 755, 3104t, 3106–3107
Hemoglobin A_2 (HbA_2), 755, 757t, 762, 762t
Hemoglobin Bart's hydrops fetalis, 763–764, 764t
Hemoglobin-based oxygen carriers (HBOC), 792
Hemoglobin C, 757t, 759f, 764, 765t
Hemoglobin E, 764, 765t
Hemoglobinemia, A6
Hemoglobin F (HbF), 755
Hemoglobin Hasharon, 765
Hemoglobin H disease, 764, 764t
Hemoglobin Köln, 765
Hemoglobin Lepore, 762t
Hemoglobinopathies
  acquired, 765
  arthropathies associated with, 2872–2873, 2872t
  HCT for, 901
  with hemoglobins with altered oxygen affinity, 765, 765t
  with M hemoglobins, 764–765, 765t
  in pregnancy, 3766
  red cell indices in, 438
  with unstable hemoglobins, 765, 765t
Hemoglobin-oxygen dissociation curve, 273, 386, 755–756, 756f
Hemoglobin S, 757, 757t, 758f. *See also* Sickle cell disease
Hemoglobin SC disease, 757t
Hemoglobinuria
  after transfusion, 891t
  march, 785, 786t
  paroxysmal cold, 786t, 787
  paroxysmal nocturnal. *See* Paroxysmal nocturnal hemoglobinuria

Nitrofurantoin
actions of, 1149, 1161, 1164t, 1165f
adverse effects of, 1154t, 1161
common, 1076t
eosinophilia, 449
folate deficiency, 773t
in G6PD deficiency, 784t
hepatotoxicity, 2584, 2589
neuropathy, 3494t
pulmonary, 2192
for cystitis, 1076, 1076t, 1077
indications for, 1157t, 1161
in pregnancy and lactation, 1152t
prophylactic, 1162t
resistance to, 1076, 1157t, 1161, 1164t, 1168
for urinary tract infections, 1201t, 1267
Nitrogen dioxide exposure, 2171t
Nitrogen mustard. *See* Mechlorethamine (nitrogen mustard)
Nitroglycerin
adverse effects of, 2041, 2057
for cocaine intoxication, 3576
drug interactions of, 472
for ergot alkaloid overdosage/poisoning, 3590t
for heart failure, 1944, 1946t, 2062
for hypertensive emergencies, 2087t
for hypothermia, 3633
intravenous, 2062
for ischemic heart disease, 2040t, 2041
metabolism of, 467
for pulmonary edema, 2256
for Raynaud's phenomenon, 2785
for STEMI, 2057, 2062
Nitroimidazole, 2447t, 2448t
Nitroprusside
for adrenergic crisis, 2087
for aortic dissection, 2106
for cocaine intoxication, 3576
for ergot alkaloid overdosage/poisoning, 3590t
for heart failure, 1944, 1946t
for hypertensive emergencies, 2087, 2087t
for pulmonary edema, 2256
Nitroprusside ketone reaction, 362
